Chapter 1

Introduction

The SM of particle physics introduced in Section 2.1 is nowadays the most accepted mathematical model used to describe the elementary particles and three of the four fundamental forces of nature (electromagnetic, weak and strong interactions). This model is quite simple in concept, but has been able to describe most of the phenomena observed in nature so far with an incredible level of precision, and made a lot of predictions that have now been proven to be true, such as the postulate of the Higgs mechanism [1, 2] followed by the discovery of the Higgs boson itself [3, 4] by the CMS and A Toroidal LHC ApparatuS (ATLAS) experiments analyzing the proton-proton collisions produced by the Large Hadron Collider (LHC) at a center of mass energy $\sqrt{s} = 13$ TeV, announced at the European Council for Nuclear Research (CERN) on the 4th of July 2012.

However, as accurate as it seems to be, this theory is known to have several shortcomings which require further investigation. Eventual exotic particles which do not fit in the current model could be the sign of new physics and have therefore been extensively searched for over the course of the last decades in order to enhance our understanding of the Universe and all its constituents.

In this context, the first serious DM hypothesis was introduced in the 1970s because of gravitational anomalies observed by several astrophysicists, as a way to explain the apparent non-luminous missing mass in the Universe [5]. Indeed, the visible mass in most galaxies appears to be way too low to explain several astrophysical processes, such as the rotation curves of the galaxies [6], which seems to be incompatible with the well established laws of gravitation. Some additional measurements of the gravitational lensing (in the Bullet Cluster, for example [7]) and the anisotropies observed in the CMB [8] are other evidences for the existence of DM, as explained in Section 2.2.

As far as we currently know from cosmological measurements, ordinary baryonic matter only constitutes around 5% of the Universe, while DM represents around 26% of the energy density of the Universe (the rest is being considered as dark energy) [9]. Understanding the nature and properties of this new kind of exotic matter is therefore crucial to try and understand the physics in the Universe, with many large experiments around the world currently involved in such searches.

Nowadays, the existence of DM is well established in the physics community, even though it has never been observed directly, since our only evidences so far for its existence come from its large-

scale gravitational effects. While its mass, spin, nature and basic properties are still unknown and extensively studied, one of the best DM candidate is the so-called Weakly Interactive Massive Particle (WIMP), predicted to interact both gravitationally and weakly with SM particles. This would allow direct and indirect detection of such candidates, used as the driving process of many of experiments over the last decades, trying to find the hint of a possible interaction between standard baryonic particles and eventual DM particles, or even between several DM particles themselves. Dark matter production through the use of a particle accelerator colliding SM particles together, such as the LHC, is also a possibility, and will be considered as the main channel towards the eventual detection of this exotic matter throughout this work. The production through colliders is actually able to provide constraints on low dark matter masses as well, in a region where both the direct and indirect searches are less efficient, which makes the LHC a perfect tool to study this kind of Beyond the Standard Model (BSM) physics. These searches will be summarized in Section 2.5.

However, observing DM is still extremely difficult, mainly because it barely interacts with ordinary baryonic matter, except through gravity (we have to assume that it does interact with SM at least weakly for the sake of this work though, as we would not be able to discover it as an individual particle if it were not the case). This means that nowadays, all the experiments searching for DM have only been able to put constraints on the DM particle mass and on the interaction cross sections between the dark and standard sectors. Actually, even if the collisions between protons produced by the LHC do have a sufficient amount of energy to produce this kind of particles, we would not expect them to interact with our detector, making their detection even harder. The eventual presence of such matter has to be inferred from the study of the interaction between SM particles and CMS itself, since a typical DM-like event consists of at least one energetic SM particle produced in association with a large imbalance in the transverse momentum due to the presence of an eventual DM candidate that was able to escape our detection.

In the context of this work, DM is searched for in association with one or two top quarks which play the role of the SM particle allowing us to trigger the event. This is indeed a perfect channel for this kind of searches if we assume that the interaction between the dark and standard sectors respect the principle of Minimal Flavour Violation (MFV), which can be consistently defined independently of the structure of the new physics model [10]. In this case, this interaction should follow the same Higgs-like Yukawa coupling structure as the usual SM baryonic particles, which actually depend on the mass: the heavier the SM particle considered is, the easier it is for it to couple with the dark sector. This makes the top quark, the most massive of all the fundamental particles observed by far, an excellent object to study in this context.

However, this also means that the phenomenology of this quark is mostly driven by its large mass and that it decays before hadronization can occur, usually into a W boson and a bottom quark. The final state of the process we are interested in is then made of some b jets, leptons and/or quarks and is categorized depending on this number of b-tagged jets and on the decay of the W itself. This work will actually be focused on the two leptons final state, also known as the dileptonic channel, mostly since this channel does not have lots of background processes raising to a similar final state, even though its branching ratio is the smallest, as will be explained in Section 2.6. Additionally,

leptons are by reconstruction much cleaner than jets: their identification and momentum calculation is easier to perform, and the uncertainties associated to these measurements will be smaller.

The LHC has now been running for 10 years, and several similar searches have already been carried out and published in the past by the CMS and ATLAS collaborations, at different center of mass energies. First of all, at 8 TeV, several searches for a pair of top quarks were published by the CMS (in association with DM in the semileptonic [11] and dileptonic [12] final states) and ATLAS collaborations [13]. Then, at 13 TeV, the ATLAS collaboration published on one hand several studies, considering different final states and different luminosities (13.3 fb^{-1} and 36.1 fb^{-1}) [14, 15, 16]. On the other hand, the CMS collaboration published a few extremely important papers for this study [18, 19]. For the first time in 2019, the results obtained by the $t/\bar{t}+\text{DM}$ and $t\bar{t}+\text{DM}$ analyses have also been combined and published using the 2016 data [20]. Our main objective is now to repeat and improve this analysis while considering the full Run II dataset, globally improving the analysis strategy and including the dileptonic final state for the first time in this combination.

After a general introduction about DM in general in Chapter 2, the experimental setup will be detailed in the Chapter 3. This will include a discussion about the LHC itself, along with a complete description of CMS, the detector used to collect the data that will be analyzed throughout this work. This data has been collected during the years 2016, 2017 and 2018 and corresponds to an integrated luminosity of $\sim 138 \text{ fb}^{-1}$, collected during the Run II of operation of the LHC and at a center of mass energy $\sqrt{s} = 13 \text{ TeV}$. In particular, a particular care will be given to the explanation of the Particle Flow (PF) algorithm, used to reconstruct the different objects used and that will be defined in the Chapter 4, while the estimation of the different backgrounds and the selection of interesting events will be detailed throughout the Chapters 5 and 6.

Distinguishing between the signal we are searching for and backgrounds having a much higher cross-section and kinematically really close, such as the SM $t\bar{t}$ without production of DM is not a straightforward task (sometimes a production of missing transverse energy due to the presence of physical neutrinos is even obtained). To isolate the signal and to obtain some discrimination between these kind of processes, an algebraic reconstruction of the event and top-notch Machine Learning (ML) techniques are used in this work, in order to train a network of neurons to perform this task. The main objective is to make them learn how to combine the discriminating power of a set of input variables in order to create a single output variable describing the probability of a single event to be classified as signal or background. All this process will be detailed in Section 6.3.

Finally, a statistical interpretation of our data will be performed and different sources of systematic uncertainties will be considered in Chapter 7. This will allow us to set upper limits on the cross section production value of DM particles in our particular channel and for the simplified models considered in this analysis. The conclusions of this work and some additional future prospects will then finally be presented in Chapter 8.

Chapter 2

The Dark Matter case

In this chapter, some general explanations about the Standard Model (SM) will first of all be given in Section 2.1 as a general introduction about today's most accepted mathematical model describing all the known particles and their interactions. The case for Dark Matter (DM) will then be presented in Section 2.2, along with a summary of the main evidences, mostly astrophysical, which lead to the introduction of this kind of Beyond the Standard Model (BSM) physics. Then, the main properties expected by such exotic matter will be introduced in Section 2.3 and nowadays's most accepted DM candidates, such as the Weakly Interactive Massive Particle (WIMP) briefly introduced previously will be presented in Section 2.4.

The main ways we have to search (direct, indirect and collider searches) for this new exotic physics along with the main experiments dedicated to such searches will then be shown in Section 2.5. Finally, the searches performed in colliders such as the Large Hadron Collider (LHC) and our particular channels of interest (DM produced in association with either one or two top quarks) will be detailed in Section 2.6 and the latest similar results and exclusion plots published over the course of the previous years by the ATLAS and CMS collaborations will be shown in Section 2.7.

2.1 The Standard Model (SM)

The Standard Model (SM) of particle physics is a relativistic Quantum Field Theory (QFT) theory which is able to mathematically summarize our current understanding of all the particles surrounding us and to describe three out of the four main interactions between these particles (mainly the weak, strong and electromagnetic forces, while an explanation of the origin of the gravitational interaction is still out of the reach of this theory nowadays).

If the neutrinos are considered to be normal Dirac fermions (and the question whether or not they could actually be Majorana particles is still well under discussion [22]), then the SM contains 26 free parameters, mainly the masses of the 12 predicted fermions, as shown in Figure 2.1, along with the couplings describing the strengths of the three interactions, two parameters describing the Higgs potential, eight mixing angles and, maybe, the phase of the eventual strong CP violation that we will

mention in Section 2.4 (but in any case this parameter is expected to be close to 0). This is a quite high number of free parameters, but the value of most of them has now been derived experimentally, to match the observations made over the last decades.

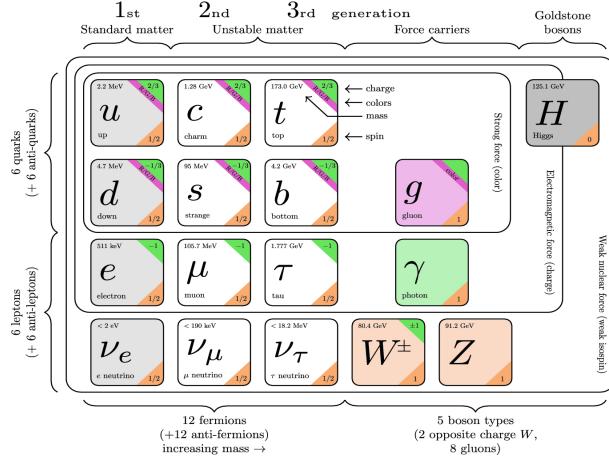

Figure 2.1: Representation of the 12 fermions of the SM [21].

The SM Lagrangian density in a differential volume element $\mathcal{L} = \int L d^3x$, accounting for the kinetic and potential energy of a system, takes the (very) simplified form given by Equation 2.1, where the $F_{\mu\nu}$ is the field strength tensor accounting for the different interactions, ψ is the interacting field describing quarks and leptons and ϕ is the Brout-Englert-Higgs field while y_{ij} are the Yuwaka couplings to this field, which depend on the mass of the particle considered and which will be described later on in Section 2.5.3.

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + i\bar{\psi}\not{D}\psi + \bar{\psi}_i y_{ij} \psi_j \phi + |D_\mu \phi|^2 - V(\phi) \quad (2.1)$$

A complete description of this model is unfortunately out of the scope of this work but it is important to note that the SM, although mostly experimental, is still working extremely well today. Indeed, it managed to make a lot of predictions over the years, which is the best you can obtain from a mathematical model, and most of its predictions revealed themselves to be true (we can quote for example that it successfully predicted the existence of the gluons, the top quarks, along with the W, Z and Higgs bosons [23]).

However, even though it now appears to be complete since all its predictions have been discovered, we know that the SM is not the final theory of particle physics since it is not able to explain all the observations which have been made. There are still today some open questions and many Beyond the Standard Model (BSM) theories trying to explain such observations which do not fit inside the SM, such as an eventual inclusion of the gravitational interaction within this model. We can quote for example as successful BSM theories the possible existence of the supersymmetry, telling us that each particle should have a superpartner whose spin differs by 1/2 or the possible existence of Dark Matter (DM) particles, the main subject of the discussion of the following sections.

2.2 At the origins of dark matter

The origin of the concept of dark matter can be traced back to the 17 and 18th centuries, shortly after Newton's works on gravitation, even though this concept changed quite a lot over the years. Back then, DM was more considered to be ordinary matter which simply did not emit any kind of electromagnetic radiation, being therefore invisible and dark, but which does have a strong impact in the gravitational point of view because of its mass. It was for example considered in the 20th century to be found in massive astronomical objects able to absorb the light or other objects located behind them, such as black holes (and even some actual theories still believe this is true!).

2.2.1 Zwicky and the virial theorem

In the 20th century, the first experimental evidences for the existence of dark matter were shown. In 1933, Fritz Zwicky managed to determine the mass of the Coma Cluster using the virial theorem [24], which states that in a cluster in equilibrium under its own gravitation the kinetic energy must be comparable to its gravitational binding energy.

Mathematically, the virial theorem can be written in Equation 2.2, where the brackets represent the mean value of the quantity obtained over time or position, the universal constants of gravitation is $G = 6.67 \cdot 10^{-11} \text{ m}^3 \text{ kg}^{-1} \text{ s}^{-2}$ and where the gravitation potential energy expression can be simplified assuming a spherical distribution of the masses and the same average density everywhere in the cluster considered.

$$2\langle T \rangle + \langle V \rangle = 0, \text{ where } \begin{cases} T = \frac{1}{2} \sum_i M_i v_i^2 = \frac{1}{2} M \langle v^2 \rangle \\ V = -4\pi G \int_0^R M \rho r dr \propto \frac{GM^2}{R} \end{cases} \quad (2.2)$$

Solving these simple equations gives us an approximate value of the mass of the cluster in Equation 2.3, where R is the radius of the cluster and $\langle\langle v^2 \rangle\rangle$ is the squared velocity of all the galaxies averaged over position and time.

$$M \propto \frac{\langle\langle v^2 \rangle\rangle R}{G} \quad (2.3)$$

From this simple expression and astronomical observations, Zwicky then managed to compute the average mass to light ratio of its galaxies and concluded that the value obtained was around 400-500 times larger than the mass previously estimated by Edwin Hubble, who simply considered the number of visible galaxies within this cluster for his calculations. One plausible explanation for this discrepancy is to introduce the concept of DM, which contributes to the mass of the cluster without increasing the galactic luminosity.

Zwicky's results were actually quite controversial since they were based on statistical calculations relying on different hypotheses not always justified, such as the fact that the galaxies in the cluster must be gravitationally bound with each other and they were actually proven to be overestimated later on [25], but additional observations came to enforce to validity of his conclusions anyway.

2.2.2 Spiral galaxies rotation curves

Despite being controversial and slightly off, Zwicky's results were soon followed by a series of additional astronomical observations leading to the same conclusion, the possible existence of non-luminous matter in all the galaxies, called dark matter. The most famous of these results is the study of the observed and expected rotation curves of the stars within spiral galaxies such as the Milky Way in the 1970s [6].

According to this study, if we assume that we can apply Newton's universal laws of gravitation at the galactic scale, then the stars within this kind of galaxies should rotate with a velocity depending on the radius to the galactic center obtained by the usual equation for centripetal acceleration in a gravitational field and represented in Equation 2.4, where $M(r)$ accounts for the total mass encountered in a radius r .

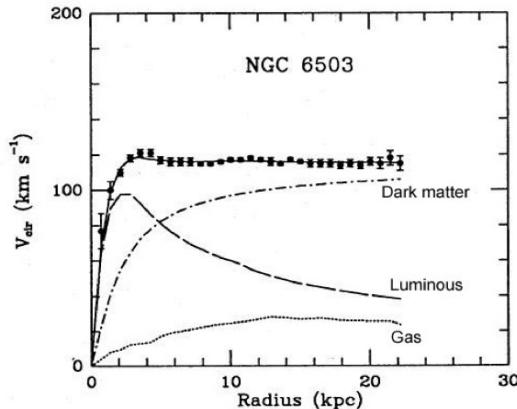

$$v_{\text{rotation}}(r) = \sqrt{\frac{GM(r)}{r}} \quad (2.4)$$

At first approximation, one can assume that most of the mass within this kind of galaxies comes from the inner core, which means that, at large radius, the velocity of individual stars is expected to decrease proportionally to $r^{-1/2}$. Any deviation to this rule suggest that either our understanding of gravity at large scales or our basic understanding of galaxies as a celestial body made of stars, dust and gas, has to be revised.

Actually, observations made by Vera Rubin and her team in the early 1970s with a new spectrograph designed to study the velocity curves of spiral galaxies with a degree of accuracy never reached before, did not confirm these expectations [26]. Indeed, according to these results, from a given value of the radius, the velocity curve appears to be flat instead of decreasing, as illustrated in Figure 2.2. This is another hint that can motivate the introduction of the concept of DM.

2.2.3 Cosmic Microwave Background (CMB) anisotropies

The CMB is a mostly uniform background of primary radio waves emitted when the Universe became transparent around 380.000 years after the Big Bang and was discovered accidentally in the 1940s [27]. Studying it is extremely important, as it is actually made of the oldest and cleanest electromagnetic radiation we can find in the Universe. Precise measurements of this radiation are actually critical in many different fields of physics, since any proposed model of the Universe must be able to explain this radiation, its temperature and anisotropies.

K.G. Begeman, A.H. Broels, R.H. Sanders. 1991. Mon.Not.RAS 249, 523.

Figure 2.2: Expected and observed rotation curves of the galaxy NGC 6503 [6]. The black dots correspond to the data and the *luminous* line corresponds to the expected rotation curve decreasing as $r^{-1/2}$, as expected from Newtonian dynamics.

Recent measurements determined that the CMB can be considered as emitting a thermal black body spectrum at a temperature of $(2.72548 \pm 0.00057)\text{K}$ [28]. However, we now know that this temperature is actually not constant as some small anisotropies (at the 10^{-5} level) depending on the value of the angular angle of observation can be observed, as represented on Figure 2.3.

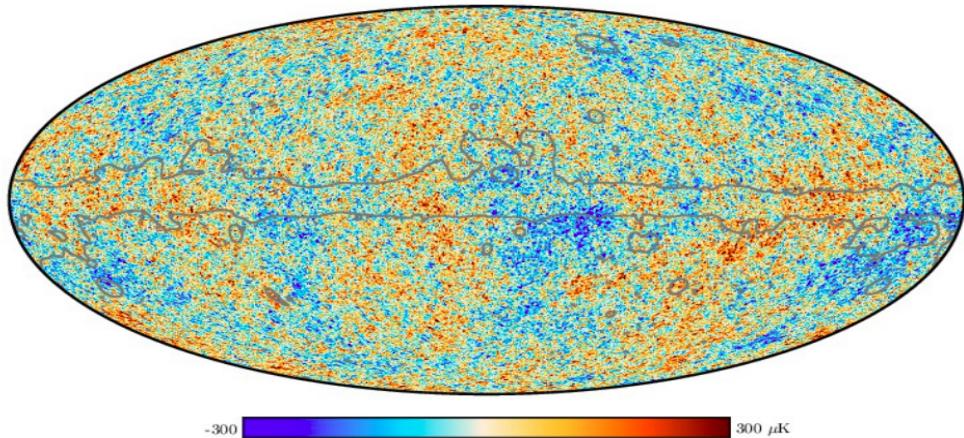

Figure 2.3: Anisotropies at the 10^{-5} level in the temperature of the CMB, as observed by the Planck satellite in 2018 [29].

We see these fluctuations projected over a 2D sphere, and it is therefore natural to introduce at this point Laplace's spherical harmonics, $Y_{lm}(\theta, \phi)$, a complete set of orthogonal functions obtained by solving Laplace's equation $\nabla\psi = 0$ on a sphere and defined by a few parameters such as l , the multipole, representing a given angular angle in the sky ($l=100$ corresponds to $\sim 1^\circ$) and m , the number of poles, such as $-l \leq m \leq l$ [30].

It is possible to show that these spherical harmonics form a complete orthonormal basis on this space and therefore that any function can be defined on the sphere may be expanded into these

harmonics using coefficients called a_{lm} . The temperature fluctuations, whose value depend on the two usual spherical angles θ and ϕ can therefore be expanded using these generic functions, according to Equation 2.5.

$$\frac{\Delta T}{T}(\theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{m=l} a_{lm} Y_{lm}(\theta, \phi) \quad (2.5)$$

The information about the anisotropies can actually be extracted from the variance of these harmonic coefficients a_{lm} of the expansion since the CMB is assumed to be a gaussian random field. The power spectrum of the CMB can therefore be extracted according to Equation 2.6, and from which most of the cosmological information of the CMB is derived.

$$D_l = \frac{l(l-1)C_l}{2\pi} = \sum_m |a_{lm}^2| \quad (2.6)$$

Interestingly enough, this spectrum is directly affected by the value of the density of the dark matter in the Universe, and this is something that will be often discussed in the remaining of this chapter. Doing a multi-parameters fit on the observed data represented in the power spectrum (cf. Figure 2.4) is then able to give us directly the energy density of baryonic Ω_b and dark Ω_χ matter, along with other important parameters of the ΛCDM cosmological model. Today's most precise measurements have been obtained in 2018 using the Plank satellite, and lead to the determination of these two quantities: $\Omega_b h^2 = 0.02220 \pm 0.00020$ and $\Omega_\chi h^2 = 0.1185 \pm 0.0015$ [31]. This is one of the strongest constraint we have on DM so far, since any DM candidate will need to comply with this measurement.

By dividing these results with the value of the scaling factor for Hubble expansion rate $h = 0.674$ [32], we can obtain from these numbers a proportion of 4.9% of ordinary baryonic matter and 26.1% of dark matter in the Universe, as announced in the introduction.

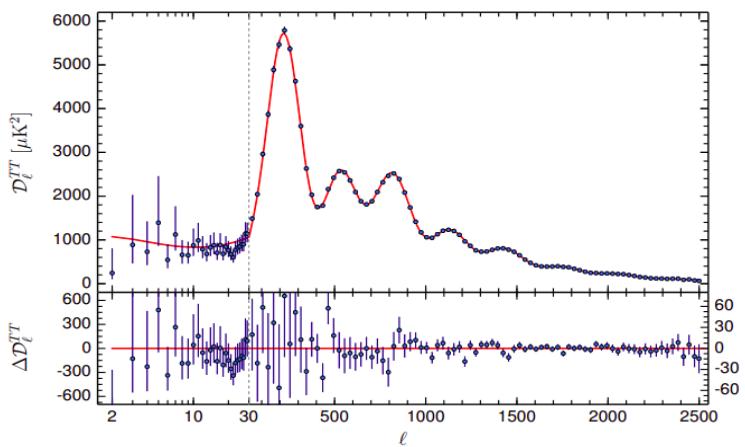

Figure 2.4: Power spectrum of the CMB obtained by Planck, representing the fluctuations of the temperature of the radiation with respect to the angular angle of observation [31].

2.2.4 Gravitational lensing

The last evidence supporting the existence of dark matter has been obtained by observing several clusters of galaxies in the Universe, such as the Bullet Cluster, and by studying their mass distribution through gravitational lensing.

The gravitational lensing effect is a consequence of the general relativity, a theory developed by Einstein as a way to represent gravity using the geometry of spacetime, stating that massive objects lying between distant sources and an observer should act as a lens and bend the light emitted by the source. This deviation of the light is actually proportional to the mass of the object in between the source and the observer, meaning that the gravitational lensing can give us a way to measure the mass distribution of massive objects, such as galaxy clusters. This mass distribution can then be compared to the luminous distribution of the cluster, to see if we can observe a discrepancy between the two measurements, which could be another hint of the existence of DM.

The bullet Cluster is particularly interesting in this context since it actually provides an evidence for the eventual existence of DM which does not rely on any mathematical assumption (other than the general relativity principle) and cannot at principle be explained by alternate laws of gravitation. In this case, some observations clearly showed that the spatial deviations between the center of the total mass and the center of the baryonic luminous mass cannot be explained with an alteration of the gravitational force law alone, with a statistical significance of 8σ [33].

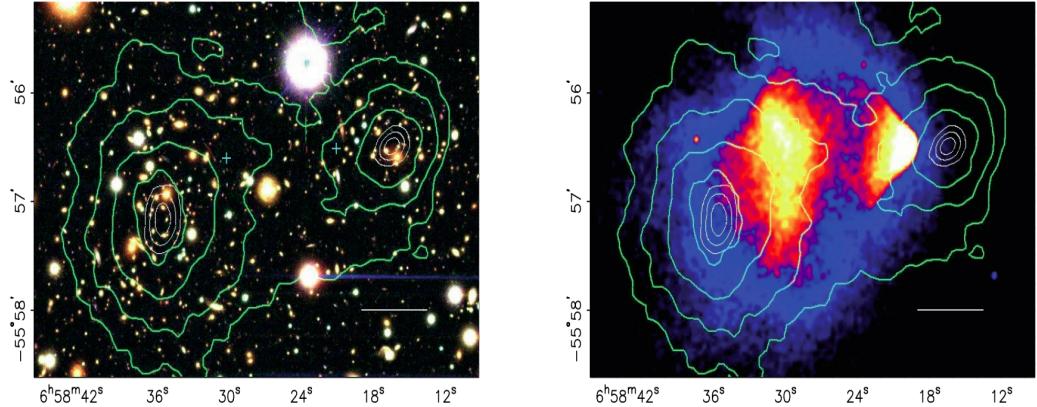

Figure 2.5: Mass distributions obtained by the Magellan in the visible (on the left) and Chandra on the X-rays spectrum (on the right) telescopes of the Bullet Cluser. Being shifted compared to each other, this is yet another clear evidence for the existence of DM [33].

As seen in Figure 2.5, the image taken by Chandra clearly shows an offset between the visible plasma of the cluster and the actual mass distribution measured through gravitational lensing (green contours). The center of the luminous mass of the cluster does not seem to match the one obtained considering its non-luminous counterpart as well, which is another evidence of the possible existence of DM within galaxy clusters.

2.3 Dark matter properties

All the previous observations allow us to list some of the most important properties that the perfect dark matter candidate should have. Even though several theories exist, each giving slightly different properties to the DM, we will consider in this work the following mostly accepted properties for such particles:

- First of all, we will assume that DM is a **particle**. As far as we know, the Universe is simply composed of particles so there is no objective reason to think that DM, being matter with a certain mass, might not be made of some kind of indivisible particles at some level.
- Then, the perfect DM candidate should of course be **dark**. This means that it should not interact at all in with electromagnetic radiation such as light, and that it should therefore be **electrically neutral**. However, it has to interact at least gravitationally because of the evidences for the evidence of such a particle explained before, mostly relying on gravitational effects, and we have to assume in this work that it interacts weakly as well to have a chance to discover it within particle accelerators.
- It has to be **non-baryonic**, mainly because the energy density for the baryonic matter obtained by observing the power spectrum of the CMB is too low to account for DM as well, as explained in Section 2.2.3. Indeed, according to these results, baryonic matter account for around 5% while dark matter accounts for more than 25% of the energy density of the Universe.
- We will also only consider **cold** dark matter, since the widely accepted Λ CDM cosmological model is actually based on this assumption. By cold, we do not refer to the temperature of these particles but actually to their size, and therefore to the velocity by which they can travel in the Universe. Large scale structures of the Universe such as we can observe them today cannot actually not be explained if DM is made of hot/relativistic particles, as represented in Figure 2.6. However, although not really as popular, it is important to note that alternative models with warm DM have also been developed and still exist today.
- It is interesting to report as well that DM particles are expected to be found near the electroweak symmetry breaking scale, between **10 GeV and 1 TeV**. This is a consequence of the expected production mechanism of such particles, the so-called thermal freeze-out.

This principle tells us that at some point in the history, DM was supposed to be in thermal equilibrium with other primordial SM particles, meaning that its production and annihilation rates were equal, as shown in Equation 2.7.

$$\chi\bar{\chi} \leftrightarrow e^+e^-, \mu^+\mu^-, q\bar{q}, W^+W^-, ZZ \quad (2.7)$$

However, because of the expansion of the Universe, at some point DM particles were simply too far apart from each other and these reactions maintaining this equilibrium were not efficient

enough any more. At this stage, the abundance of DM became fixed: this is the freeze-out, as represented in Figure 2.7.

This principle is interesting because, as a rule of thumb, we can say that if a particle interacts heavily, it will stay longer in equilibrium and its freeze-out abundance will therefore be smaller, so there is a mathematical relation between the strength of the SM/DM interaction g , the mass of the DM particle m_χ and its relic abundance Ω_χ that has been precisely measured, as expressed in Equation 2.8 [34].

$$\Omega_\chi \propto \frac{m_\chi^2}{g^4} \quad (2.8)$$

By using a typical value for g of the order of the Fermi coupling constant $G_0^F \simeq 4.54 \cdot 10^{14} \text{ J}^{-2}$ we can see that, in order to observe a freeze-out abundance comparable to the one observed recently by the Planck satellite, the DM candidate should have a mass between 10 GeV and 1 TeV as previously stated. The measurement of the CMS power spectrum is therefore able to put constraints on the DM cross-section with the baryonic sector, and all the DM candidates quoted in Section 2.4 will have to respect this criteria.

In any case, DM is not expected to have a mass lower than 300 eV since at this scale, the phase space density that would be needed to explain this relic abundance of DM would simply violate the Pauli-exclusion principle [37].

- Finally, the DM particles should be **long-lived**. Indeed, we expect that they were produced 13.8 billion years ago during the Big Bang, but it seems they are still present in the Universe since we still see their effect today. They should then be stable particles, or their lifetime should at least be larger than the age of the Universe itself.

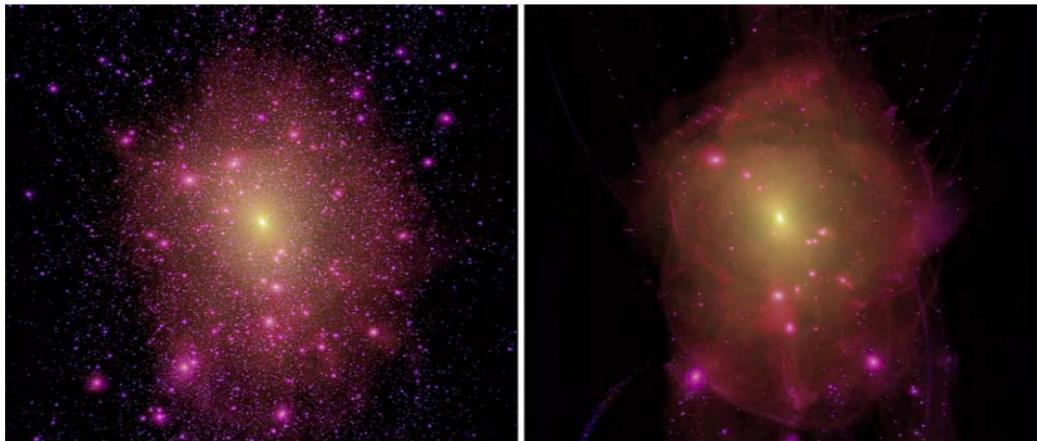

Figure 2.6: Computer simulations for cold (on the left) and warm (on the right) DM scenarios and their impact on a galactic halo at 0 redshift [35].

All these properties narrow quite a lot the number of possible DM candidates, as we will now see in the following section.

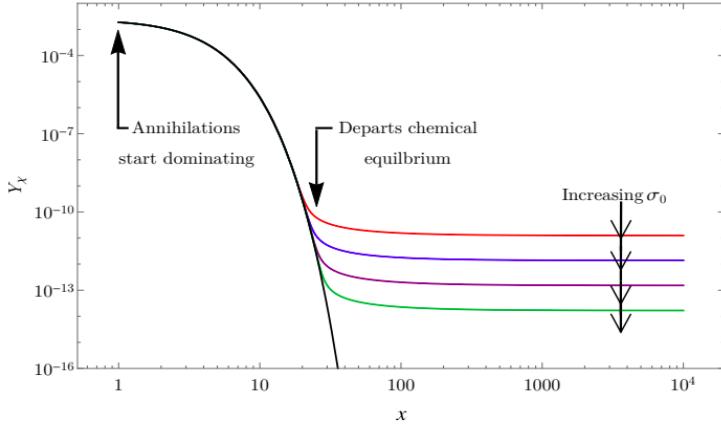

Figure 2.7: Schematic representation of the freeze-out process, representing the abundance of a 500 GeV DM as Y_χ with respect to the time and the impact of increasing cross-section annihilation values on this freeze-out abundance [36].

2.4 Dark matter candidates

Several different categories of particles could pretend to be good candidates for dark matter but only the most interesting ones will be quoted here, since an extensive list of all the different possible candidates is out of the scope of this work. Two SM particles will first of all be investigating, before introducing some BSM theories giving us additional DM candidates with the expected properties.

Massive Compact Halo Objects (MACHOs)

The first obvious DM candidate are the so-called MACHOs. These objects are massive astronomical non-luminous bodies (such as black holes) made of baryonic matter and very hard to detect, that could be responsible of the gravitational lensing observed and that could explain the apparent missing mass in the Universe. However, as we saw in Section 2.3, DM is not expected to be made of such ordinary matter, mainly because observational data of the CMB and the deduced baryonic density of energy in the Universe is able to rule out this possibility.

Several different experiments did try to search for such DM anyway, and managed to constrain the properties of this kind of objects. The main way to search for such massive objects is through their gravitational lensing effect (actually, we talk about microlensing in this case since this effect is small) since, according to the general relativity principle, they should bend the light of luminous objects located behind them, such as stars, and this bending actually depends on the mass of the eventual MACHO. Experiments like the MACHO project and EROS observed in this context $\Theta(10^7)$ stars for several years, looking for microlensing events in order to constrain this particular DM model. Results published in 2000 from the MACHO project, after studying almost 12 million stars, actually observed between 13 and 17 such events, lower than expected if DM was only made of MACHOs.

The collaboration actually managed to exclude at the 95% Confidence Level (CL) the possibility of the dark halo to be entirely made of such baryonic particles [38]. On the other hand, the EROS collaboration only observed 1 microlensing after studying more than 30 millions of bright stars during 6.7 years, while ~ 39 events were expected [39]. Both results have also been combined in order to obtain the exclusion plot represented in Figure 2.8. From this study, MACHOs with low masses ($10^{-7} M_\odot < m < 10^{-3} M_\odot$) should make up less than 25% of the dark matter halo for most models considered at the 95% CL [40].

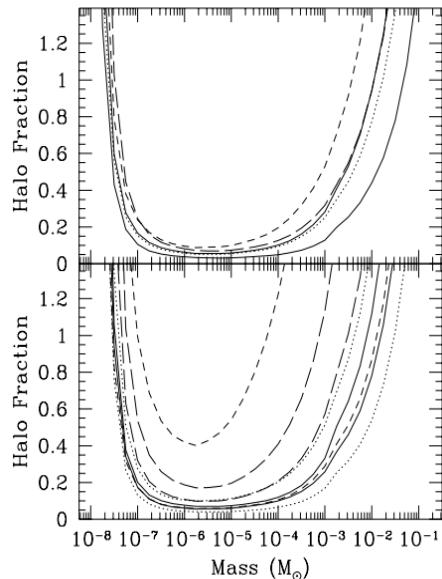

Figure 2.8: Halo fraction upper limit at the 95% CL compared to the mass of the lensing object for different MACHO models considered by the EROS (on the top) and the MACHO (on the bottom) collaborations [40].

Active neutrinos

SM *active* neutrinos ν (as opposed to *sterile* neutrinos, that will be the subject of the discussion in the next section) have been considered as good DM candidates for a long time as well, since they are electrically neutral and long-lived SM particles, two important properties of any DM candidate. They have a few particular properties that might be interesting in this context.

- First of all, even though it has still not been measured precisely, the sum of their mass has recently been measured to be lower than 0.17 eV at the 95% CL from cosmological studies [44]. Even though this is not quite understood, this is incredibly low compared to other SM particles, this particularity usually being referred to as the *mass puzzle* of the neutrinos.
- Their low mass has a consequence in the sense that it means that the gravitational interaction between two neutrinos is usually considered to be negligible and that we can consider that they only interact weakly, making it hard to study their properties. Their actual cross-section of

interaction, as represented in Figure 2.9 and which of course depends on their energies and on the channel of interaction (neutral or charged current considered), is therefore usually extremely low, making it hard to detect neutrinos.

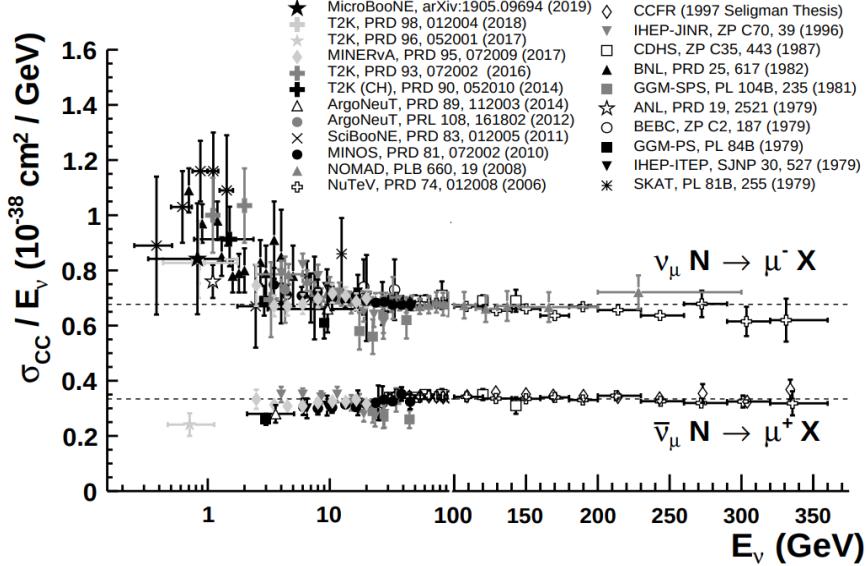

Figure 2.9: Neutrino cross section of interaction from the charged current as measured by different experiments over a large range of energies, for both neutrinos ν and antineutrinos $\bar{\nu}$ [41].

This figure clearly shows that an approximate value of the cross section for such neutrinos is of the order of magnitude of $10^{-38} \text{ cm}^2 \text{ GeV}^{-1}$, which is typically tens of orders of magnitude lower than the interaction cross section of a photon ($\sigma_\gamma \sim 10^{-25} \text{ cm}^2$ [42]). This means that the typical neutrinos of a few MeV produced by nuclear reactors have a mean free path of approximately 10 light years in steel.

- Neutrinos are also the only SM particle only observed in their left-handed chirality state, while anti-neutrinos can only be observed in their right-hand state. This could mean two things: either right-handed neutrinos do not exist in nature for some reason, or we have just not been able to detect them because their interaction with baryonic matter is too weak. Right-handed neutrinos, also referred to as *sterile* neutrinos, do not fit in the current SM but could actually also be a strong BSM DM candidate, as we will discuss in the next subsection.
- Finally, neutrinos can oscillate, a quantum phenomena according to which the flavor of a neutrino can spontaneously change with time. This means that the three interacting states ν_α observed are actually composed of several mass eigenstates ν_i , as related in Equation 2.9, where these states can be related using the Pontecorvo-Maki-Nakagawa-Sakata matrix $(V_\nu)_{\alpha i}$.

$$\nu_\alpha = (V_\nu)_{\alpha i} \nu_i \quad (2.9)$$

This effect does not however at principle have anything to do with the fact that neutrinos can be considered DM candidates, so this subject will not be discussed further in this work.

However, two physical reasons can explain why we do not really believe that DM could be made of neutrinos any more. First of all, their relative abundance does not match the expected one for DM from the freeze-out mechanism explained in Section 2.3. Indeed, their freeze-out abundance can be computed quite easily from Equation 2.10 [43], where the sum of the masses of the three neutrino flavors has been calculated to be lower than 0.17 eV [44] instead of the 11.5 eV expected to obtain the correct DM relic abundance as observed today from the power spectrum of the CMB.

$$\Omega_\nu h^2 = \sum_{i=1}^3 \frac{m_{\nu_i}}{93 \text{ eV}} \quad (2.10)$$

Additionally, for several reasons explained in Section 2.3, a good DM candidate is expect to be cold, i.e. non-relativistic. However, being extremely light, neutrinos are expected to be ultra-relativistic and could therefore not be responsible of the emergence of large scale structures as observed today. We can therefore most probably rule out the possibility of DM being made of SM neutrinos.

Sterile neutrinos

The most obvious SM particles being rules out as DM candidates, it is now time to introduce some of the most famous BSM theories introducing additional particles that could have the properties searched for. The first one of these theories introduce the so-called sterile neutrinos, usually referring to right-handed SM neutrinos, as discussed in the previous subsection.

If they exist, sterile neutrinos are expected to interact in an even weaker way than SM active neutrinos, they could be very long-lived as well and in principle, nothing prevents us from considering that they could have a mass superior to 0.4 keV, giving therefore the correct DM relic abundance [37]. A superior bound of 50 keV on such particles can also be obtained considering limits on the observation of the monochromatic decay γ line originating from the one loop radiative decay $N \rightarrow \nu + \gamma$ of such particles.

Several experiments are already searching for such particles at this level of energy. Most of these experiments focus on the analysis of γ -rays and are actually searching for this particular monochromatic line resulting of the decay of sterile neutrinos. Two independent groups actually announced in 2014 the observation of an unidentified emission line at 3.57 keV (Figure 2.10) which did not match any known atomic emission line and which is actually consistent with an eventual DM signal [45, 46], since most of the possible instrumental contamination effects have been ruled out over the course of the last few years.

However, some additional studies of the galactic center pointed out the fact that this observation might actually come from the observation of a potassium K XVIII transition line [47]. Recent observations actually ruled out at the 99% CL an eventual DM origin for this particular line [48], but further studies are still ongoing.

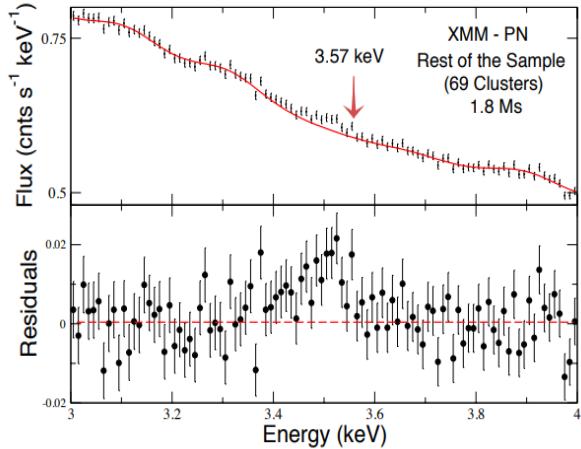

Figure 2.10: 3.57 keV emission line detected with a 4.5σ CL by the XMM-Newton telescope in 2014, which could be a hint of the presence of DM [45].

Axions

Axions could also explain the particle nature of DM, since their existence could explain 100% of the DM in the Universe, unlike most of the other candidates presented so far. Axions are hypothetical stable neutral particles, with masses of the order of the meV, introduced as a consequence of the strong-CP violation issue of Quantum ChromoDynamics (QCD). This issue is the following: the usual Θ term of the QCD Lagrangian shown in Equation 2.11 [49] should be responsible of breaking the CP symmetry, but this effect has actually never been observed so far: this is the so-called the strong CP problem.

Two ways to explain that we never observed this phenomena exist: the first is to assume that one of the quarks of the SM is massless but this does not match the current observations and measurements. The second consists in assuming that the parameter Θ , the QCD vacuum angle, is small enough so that this term becomes negligible. However, by definition, the Θ angle should be between 0 and 2π , so there is no physical reason for this parameter to be small, unless some new physics can be introduced, as the one developed in 1977 by Peccei and Quinn [50] by relaxing Θ from a parameter to a dynamic variable and absorbing it through the introduction of a new pseudoscalar particle that was called the axion.

$$\mathcal{L}_\Theta = \frac{\Theta}{32\pi^2} \epsilon_{\mu\nu\rho\sigma} G_a^{\mu\mu} G_a^{\rho\sigma} \quad (2.11)$$

By definition, it is possible to show that axions satisfy two of the previous criteria for a good DM candidate, since they are non-relativistic and their abundance might be enough to account for the dark matter energy density observed, since their actual abundance can easily be computed from Equation 2.12 [51], from which we could conclude that an axion having a mass of ~ 20 μ eV could

account for the DM relic density of the Universe, as observed today.

$$\Omega_a \simeq \left(\frac{6\mu\text{eV}}{m_a} \right)^{7/6} \quad (2.12)$$

Several axions searches experiments have therefore been set up, such as the Axion Dark Matter Experiment (ADMX), a resonant microwave cavity installed at the University of Washington, CERN Axion Solar Telescope (CAST), a CERN experiment observing the Sun which came online in 2002 and which managed in 2014 to turned up definitely the existence of solar axions [52], or the International Axion Observatory (IAXO), whose aim would be to search for axions with a much better signal to ratio noise than CAST. All the results obtained by these experiments along with their future projections are represented in Figure 2.11.

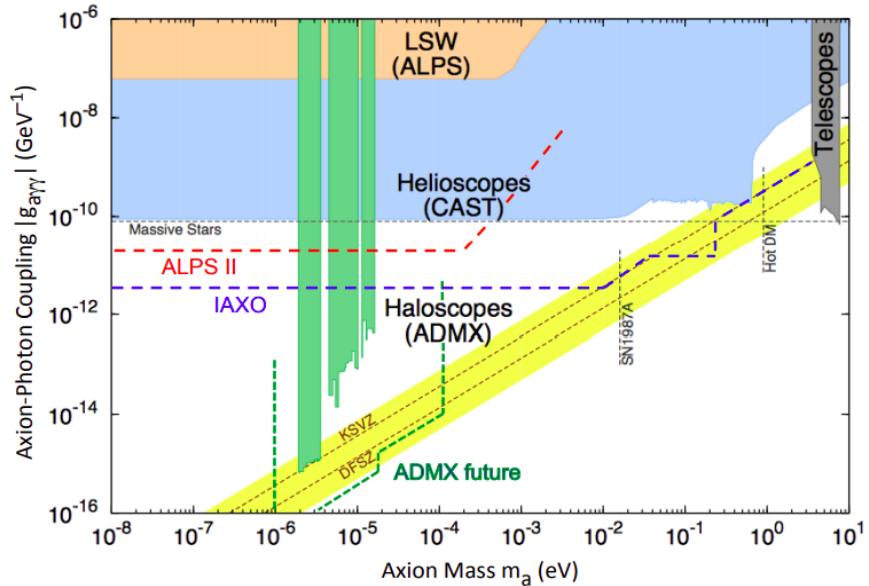

Figure 2.11: Axions exclusion plot summary and projected coverage of axion searches experiments, such as ADMX, CAST and IAXO [51].

Weakly Interactive Massive Particles (WIMPs)

The actual DM candidate that will be mostly considered throughout this work are the so-called Weakly Interactive Massive Particles (WIMPs), which are expected to interact, even though very weakly, with ordinary baryonic matter and which have an expected mass in the range of 100 GeV to 1 TeV for reasonable electroweak production cross-section values, right where we expect DM to be found from its relic density: this is the so-called "WIMP miracle", an important concept that can be translated mathematically as well. Indeed, because of the freeze-out scenario explained in Section 2.3, we can find an expression relating the relic abundance of DM Ω_χ with its annihilation

cross section $\langle\sigma_A v\rangle$ through Equation 2.13 [59].

$$\Omega_\chi h^2 \sim \frac{3 \cdot 10^{-27} \text{ cm}^3 \text{ s}^{-1}}{\langle\sigma_A v\rangle} \quad (2.13)$$

This equation implies that, since we do know the current abundance of DM in the Universe, the total annihilation cross section of DM should be equal to $\sim 3 \cdot 10^{-26} \text{ cm}^3 \text{ s}^{-1}$, which corresponds to the typical value given by WIMPs for a range of dark matter masses matching the expected one.

Several strategies can be used to detect such particles, as we will now see in the Section 2.5. This kind of particle basically arises in various BSM theories, such as the lightest supersymmetric particle in SUSY. According to this theory, each SM particle should have a superpartner whose quantum numbers would be identical except for their spins, which would differ by one half. All of these superpartners would then be potentially new and undiscovered particles, giving us a perfect DM candidate in most of the Minimal Supersymmetric Standard Model (MSSM) theories, the neutralino χ .

The WIMPs are also interesting in the sense that introducing them in the terms of this supersymmetric theory would not only give us a strong DM candidate, but would also solve the hierarchy problem, the apparent large discrepancy between multiple aspects of the weak and gravitational forces (10^{24} less times stronger).

2.5 Dark matter searches

As previously stated, several cosmological evidences allow us to introduce the concept of dark matter, but its properties such as its mass, coupling and interaction cross-section are difficult to study in this context. Several different ways can then be used in order to try and detect DM particles in order to study them, as represented in Figure 2.12, strategies which can usually be divided into three categories: the direct and indirect searches, mostly relying on the production of baryonic matter from the interaction between two DM particles or on the observation on the interaction between the dark and baryonic sectors, and the production in colliders, usually able to probe lower DM candidates masses and which will actually be the main focus of this work.

A discussion about these different detection strategies along with the main results obtained by different experiments in each case will now be presented.

2.5.1 Direct searches

From cosmological observations, we know that we live in a halo of dark matter. In this case, WIMPs should cross the Earth every day and, even if they interact only weakly, we should be able to directly detect them through their interaction with ordinary baryonic matter, for example because of their

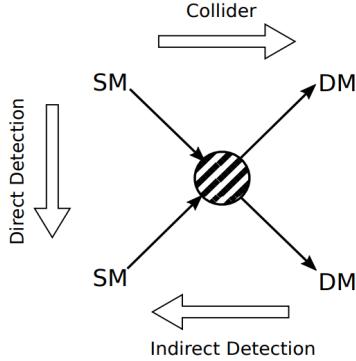

Figure 2.12: Schematic view of the three main DM detection strategies: direct, indirect and collider production searches [53].

scattering with the nuclei of these particles. Indeed, the transfer of momentum between these two particles in this case might be detectable with the correct experimental device, typically placed deep underground to have the lowest possible background, which is the main source of perturbations of such experiments.

To study this particular category of searches, let's first of all introduce the rate of expected WIMP scattering off a target nucleus of mass m_N with Equation 2.14, rate which ends up being described by a simple steeply falling exponential function as shown in Figure 2.13 [54], where E_{nr} is the nuclear recoil energy measured, m_χ is the WIMP mass, σ its cross section, $\rho_0 = 0.3 \text{ GeV cm}^{-3}$ is the local dark matter density and $f(v)$ the normalized WIMP velocity distribution.

$$\frac{dR}{dE_{nr}} = \frac{\rho_0 M}{m_N m_\chi} \int_{v_{\min}}^{v_{\text{esc}}} v f(v) \frac{d\sigma}{dE_{nr}} dv \propto \exp\left(-\frac{E_{nr}}{E_0} \frac{4m_\chi m_N}{(m_\chi + m_N)^2}\right) \quad (2.14)$$

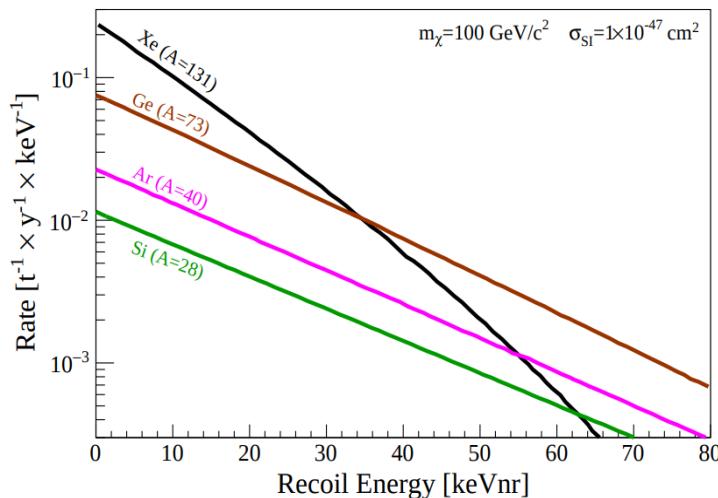

Figure 2.13: Nuclear recoil spectra induced in different materials for a given DM WIMP of 100 GeV, assuming a WIMP-nucleon Spin Independent (SI) cross section [54].

From this relation, the Equation 2.15 can be easily derived, representing this time the number of expected DM events in an experiment running during a time T , where $\epsilon(E_{nr})$ is the efficiency of the detector for a given recoil energy.

$$N = T \int_{E_{\min}}^{E_{\max}} \epsilon(E_{nr}) \frac{dR}{dE_{nr}} dE_{nr} \quad (2.15)$$

The maximal velocity V_{esc} used as superior bound of the integral in Equation 2.14 has actually been measured to be in the range [498 – 608] km/s at the 90% CL [55], since any particle having a velocity higher than this would not be bound any more to the gravitational potential of a galaxy. This has an important consequence: all the direct and indirect detection experiments actually need to take into account is the annual modulation of the observed count rate, due to the movement of the Earth around the Sun, as shown in Figure 2.14 [56], since this velocity is not negligible compared to the escape velocity v_{esc} .

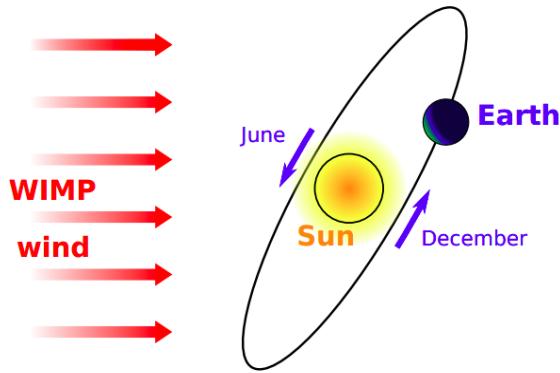

Figure 2.14: Schematic representation of the annual modulation of the WIMP wind introduced by the motion of rotation of the Earth around the Sun [56].

From our perspective, it seems indeed that the velocity of the speed of WIMP particles arriving is changing depending on the month of the year, since the Earth is sometimes moving in the direction of the WIMP source, and is sometimes moving away: the maximal velocity is reached around June. This is extremely important to take into account this effect since, as we saw on the previous equations such as Equation 2.13, the count rate of incoming particles $N(t)$ actually depends on this velocity, and this modulation then introduces a periodical modulation that we need to take into account, as shown in Equation 2.16, where the periodical part usually introduces a $\sim 5\%$ deviation [54].

$$N(t) = B + N_0 + N_m \cos(\omega(t - t_0)) \quad (2.16)$$

This effect is also important because an experiment performed during a long period of time can actually help us finding an eventual hint of DM particles, since our signal is expect to follow this

periodical deviation while the background is expected to be constant. Moreover, this WIMP wind is expected to come from a particular region of the sky while the backgrounds are expected to be distributed uniformly, so this gives a clear way to isolate the signal.

Finally, it is also important to note that two different kinds of direct searches can be defined, depending on the category of the scattering between the DM and the nucleus: the Spin Independent (SI) (proceeding through the scalar term) and Spin Dependent (SD) (proceeding through the axial term of the Lagrangian) searches, since the interaction cross section σ of Equation 2.14 is expected to be different for DM particles having a spin 0 or not, as shown in Equation 2.17, where F is a factor accounting for the dependence of the scattering on the energy. This means that results obtained by either hypothesis can usually not be compared with each other.

$$\frac{d\sigma}{dE_{nr}} \propto \sigma_{SI} F_{SI}^2(E_{nr}) + \sigma_{SD} F_{SD}^2(E_{nr}) \quad (2.17)$$

As previously stated, many experiments are dedicated to the direct search of DM particles, but in order to isolate an eventual DM signal, an environment with an ultra-low background is usually required, which can usually be reduced either by placing the detector underground (to reduce the contamination due to the cosmic rays), by increasing the statistics or by choosing carefully the active material of the detector (to reduce the internal background coming from the detector itself). The impact these kind of parameters have on the final limits can be seen in Figure 2.15.

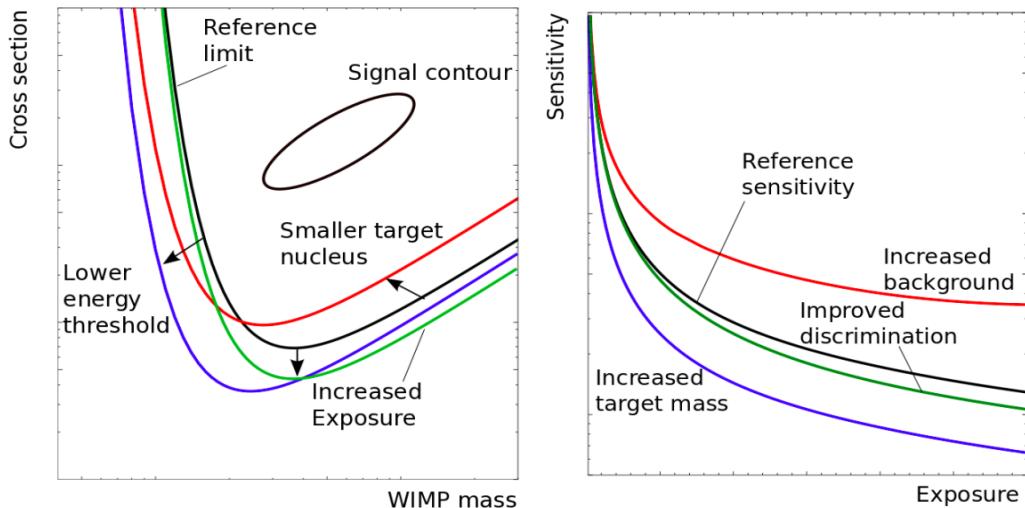

Figure 2.15: Impact of different experimental parameters on the final limits depending on the cross section and WIMP mass (on the left) or sensitivity and exposure (on the right), with respect to the expected limits (black curve) [57].

These detectors try to detect the scattering of an unknown exotic particle with an ordinary nucleus, which typically can give rise to different categories of signals. Some detectors try for example to detect the direct ionization of the target atom, while others focus on the emission of light coming from the desexcitation of the scattered nucleus, and some even search for the heat produced by these

collisions under the form of phonons in a crystal. All these different search strategies have been summarized schematically in Figure 2.16.

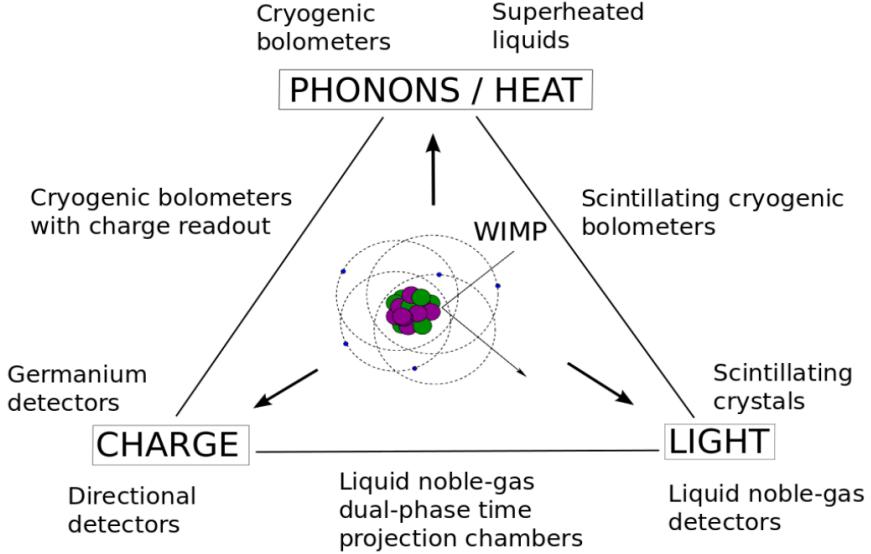

Figure 2.16: Schematic representation of the three main strategies to detect directly the interaction between DM particles and an ordinary nucleus [57].

As of today, no direct experiment has been able to detect serious hints for the existence of DM, and they have only been able to set limit on the scattering cross section depending on the models parameters, as seen on Figure 2.17 for multiple experiments at once.

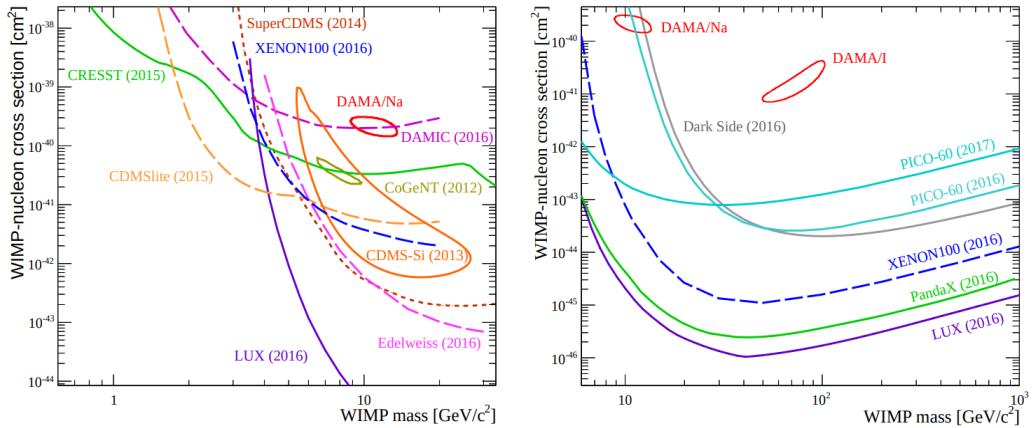

Figure 2.17: Exclusion limits obtained by various direct detection experiments considering a SI interaction cross section for low WIMP (on the left) or high WIMP masses (on the right) [57].

However, the DAMA experiment at the Laboratori Nazionali del Gran Sasso (LNGS) did find an interesting result by showing the hints of an annual modulation signal compatible to the expected one due to the WIMP wind in the 2-6 keV energy range, as seen on Figure 2.18 [58]. Further investigations about this modulation are still ongoing today, since no systematic effect able to account for the

observed modulation amplitude and to simultaneously satisfy all the requirements of the signature has been found so far.

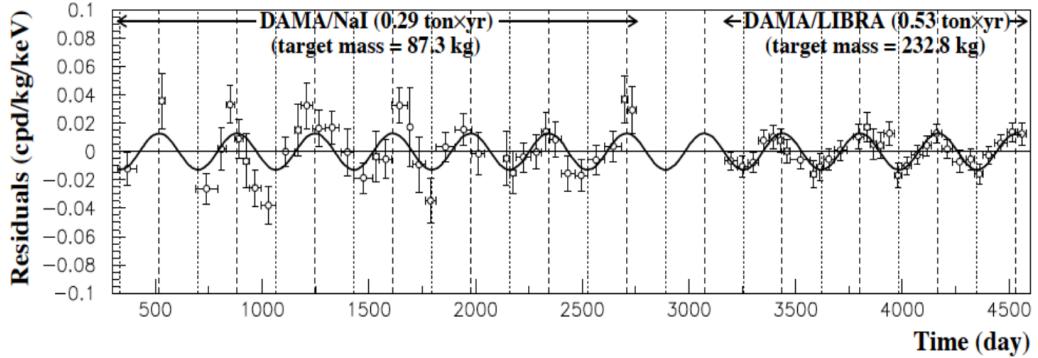

Figure 2.18: Observed and expected annual modulation in single hits events in the 2-6 keV energy range by the DAMA experiment [58].

2.5.2 Indirect searches

The indirect detection of DM particles consists basically in searching for SM products coming from the annihilation of two DM particles or from its eventual direct decay, usually under the form of a flux of γ -rays, neutrinos, cosmic-rays or anti-matter appearing as an excess over the expected background. Indeed, many extensions to the SM, such as the supersymmetry SUSY or Universal Extra Dimensions (UED) do provide solid DM candidates (the lightest supersymmetric particle and the lightest Kaluza-Klein state, respectively) expected to interact with each other, resulting in the immediate production of SM (un)stable particles that can be detected by telescopes either placed on the ground or directly in space. Another point to make is that indirect searches are also usually affected by the annual fluctuation induced by the movement of the Earth around the Sun, as explained in the previous Section 2.5.1.

Indirect searches are actually extremely useful since they are sensitive to the DM annihilation cross section, mass and the density profile of DM halos $\rho(\vec{r}(s, \Omega))$, usually represented by a Navarro-Frenk-White (NFW) profile, as shown in Equation 2.18 [60], where $r_s = 20$ kpc is the scale radius of the DM halo for the Milky Way and r is the distance to the center of the cluster considered, assumed to be spherical in this case.

$$\rho(r) \propto \frac{r_s}{r \cdot \left(1 + \frac{r}{r_s}\right)^2} \quad (2.18)$$

The flux coming from the annihilation of two DM particles is then expected to be proportional to its annihilation cross section σv , the solid angle of observation Ω and the number of particles emitted by this annihilation $\frac{dN}{dE}$, according to Equation 2.19, where the integration is done over the line of

sight l and the solid angle of observation Ω .

$$\frac{d\Phi}{d\Omega dE} = \frac{\sigma v}{8\pi m_\chi^2} \cdot \frac{dN}{dE} \iint_{l,\Omega} \rho^2(\vec{r}(s, \Omega)) dl d\Omega \equiv P \cdot J(\Delta\Omega) \quad (2.19)$$

This equation is extremely important for two reasons. First of all, it shows that, if a signal is found in direct detection, we could use this detection to determine the new object mass and scattering cross section and then use this information in order to obtain the DM density profile this way: the data obtained by the different strategies of detection are actually complementary. The second reason is that as we can see, the flux of incoming particles can actually be divided into two factors: P , entirely dependent on the physics of the DM particle, and the J-factor $J(\Delta\Omega)$, depending only on the distribution of DM within the system considered. This J-factor is in this sense actually a measurement of the quality of an astronomical object for an indirect measurement, since the higher the flux received, the better the measurement will be in general (even though this is not the only factor which matters, since for example the galactic center has a higher J-factor than the best dwarf galaxy observable, but also has a lot of backgrounds affecting the measurement).

As different channels of observations are available for us to analyze the eventual annihilation of DM, several strategies can be used in order to detect DM indirectly, as we will now see, by searching different kind of SM particles. Anyway, all these strategies have one goal in common: try to reduce the background, since the signal searched for is usually quite low while the uncertainties associated to the background in astrophysics are usually quite high.

Through γ -rays detection

The golden channel for such searches are through the production of γ -rays by DM annihilation $\chi\chi \rightarrow \gamma + X$ or decay $\chi \rightarrow \gamma + X$, mainly because the energy scale of the WIMPs implies that most of the annihilation and decay radiation will be emitted in this range of energies and because γ -rays are usually not deflected when traveling to the observer (this means that the exact source of this kind of radiation can be quite easily and precisely pin-pointed). However, they do have one drawback as well: the Earth's atmosphere is usually opaque to this kind of radiation at this level of energy. This means that most of experiments searching for them simply cannot be performed from the ground and have to be sent to space.

One of the most famous detectors of this category is the Fermi Large Telescope (LAT), a pair production detector launched in June 2008 and mostly sensitive to γ -rays between 20 MeV and 300 GeV [61]. This experiment has managed to exclude a large portion of the phase space, as seen in Figure 2.19. The GAMMA-400 experiment, whose launch is scheduled in 2020, will pick up the work of LAT, by studying a similar range but with a much improved angular and energy resolutions [62].

It is much harder for DM to produce high energy γ -rays and therefore, the flux of such particles decreases quite quickly with energy, making it harder to study since telescopes then need a much

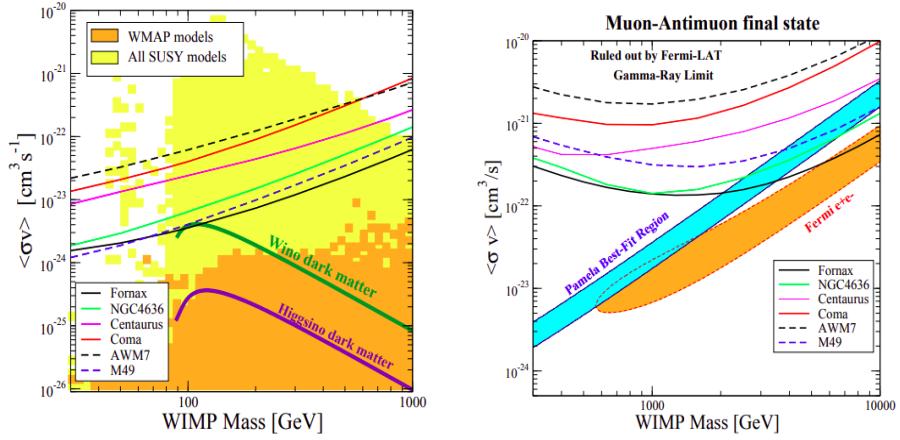

Figure 2.19: Upper limits on the DM annihilation cross section considering $b\bar{b}$ (on the left) and $\mu^+\mu^-$ (on the right) final states as a function of the WIMP mass, for different clusters studied [61].

larger effective area to pick up the same quantity of signal, and have therefore to be put on the ground. Such telescopes do exist, are called Imaging Atmospheric Cherenkov Telescopes (IACT) and have to take into account the atmospheric perturbations to work in an optimal way. They are usually sensitive to a range of energies going from ~ 10 GeV up to ~ 100 TeV, but can usually only study a small portion of the sky (up to a few degrees), forcing these experiments to choose carefully the objects to be studied. The Cherenkov Telescope Array (CTA) is a brand new telescope of this kind whose construction is supposed to start this year, that should improve greatly the sensitivity of high masses indirect DM searches.

Through neutrinos detection

Interacting only weakly, neutrinos are another reliable source of data in the Universe since they are not supposed to be altered when traveling large distances as well, even though detecting neutrinos is usually much harder than detecting γ -rays and usually involves huge tanks of water in which neutrinos can produce a Cherenkov effect that will eventually be detected.

The most famous detector of this kind, the IceCube neutrino observatory, actually uses the ice of the South Pole instead of water to detect these particles with photo-detectors, mainly because of the low interaction cross section of the neutrinos which then require the installation of a huge volume of material to increase the probability of interaction. Super-Kamiokande (Super-K), in Japan, is another large Cherenkov experiment dedicated to the detection of cosmic neutrinos. Both detectors are also largely involved as direct searches experiments, since they are also sensitive to the eventual recoil between DM and ordinary matter nuclei.

The problem with this kind of experiment is the difficulty of actually detecting some neutrinos, along with the background levels from atmospheric neutrinos, as represented in Figure 2.20, typically several orders of magnitude larger than the signal. Several strategies therefore need to be put

in place in order to reduce the background level in such experiments, such as the study of the directionnality of the source and an appropriate choice of angle of observation, since most of the contamination is coming from tau neutrinos, themselves originating from muon neutrinos oscillation, strongly suppressed around the zenith.

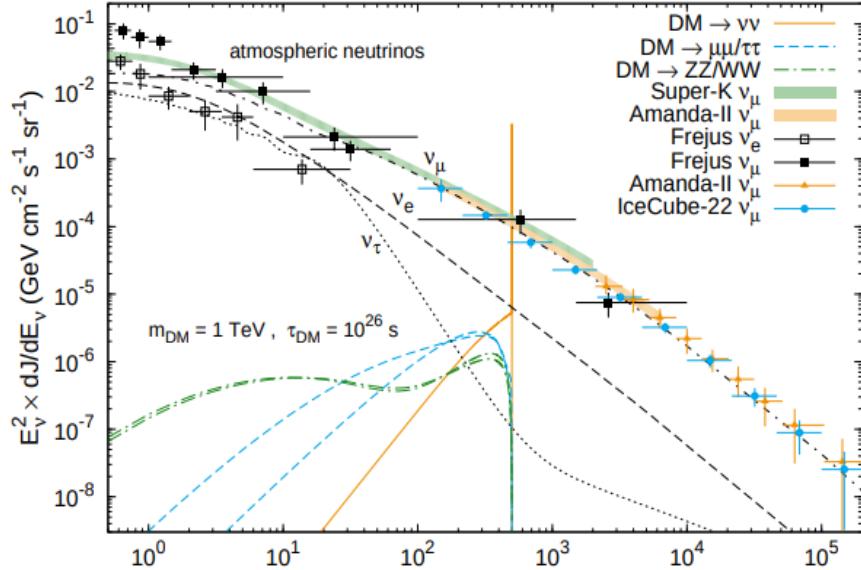

Figure 2.20: Neutrino spectra for a scalar DM candidate of 1 TeV for different indirect detection experiments and the corresponding background level expected [63].

Through cosmic rays detection

Searching for anti-matter in the cosmic rays presents the advantage of being highly sensitive, because of the low levels of backgrounds this kind of searches implies. However, cosmic rays are affected when traveling through the Universe, and determining the exact location of their emission can be quite challenging.

Among the most famous detectors of this kind, we can quote PAMELA, a spatial telescope dedicated to the study of such cosmic rays since 2006. CERN's Alpha Magnetic Spectrometer (AMS), installed in the International Space Station has also studied such radiation from a range of a few hundred MeV up to 1 TeV. The data collected by this detector is compared to the exclusion limits obtained by the IceCube detector in Figure 2.21.

2.5.3 Collider production

In this particular kind of searches, we are particularly interested in the eventual direct production of DM candidates following the collision between two highly energetic SM particles, a perfectly viable scenario if we keep assuming that DM should at least interact weakly with ordinary matter if we

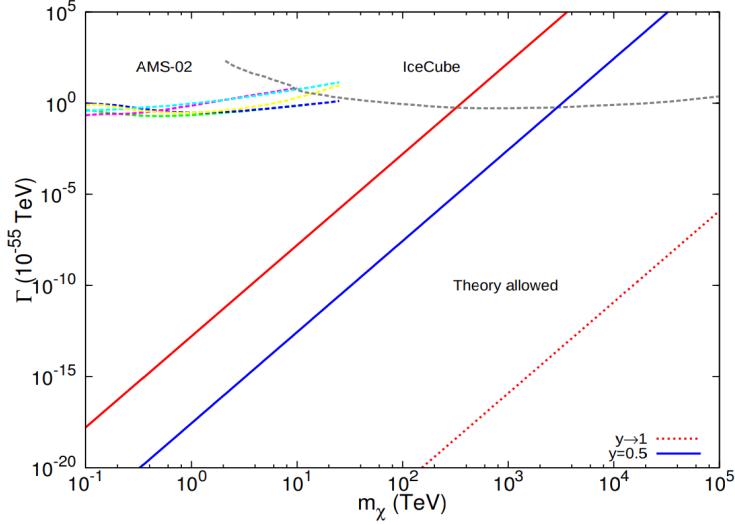

Figure 2.21: Limits of the decay width of the interaction with respect to the DM mass obtained by both IceCube and AMS [64].

want to be able to produce or detect it in a laboratory.

In this case, two main models for the interaction between SM and DM particles can be considered, each with a different level of complexity and different possible applications:

- The Effective Field Theory (EFT) approach is usually considered to be the easiest and most simplified one, even though it can still give us plenty of information about this kind of interaction. It relies on a strong assumption, assuming that the energy scale of the new exotic physics is much larger than the actual energy accessible with our experiment, since the momentum transfer of this interaction needs to be much smaller than the mediator mass for this simplified approach to be valid.

According to this approach, represented in Figure 2.22, the interaction can be described using simplified operators (the most simple ones being either scalar $\bar{\chi}\chi\bar{q}q$, pseudoscalar $\bar{\chi}\gamma^5\chi\bar{q}\gamma^5q$, vector $\bar{\chi}\gamma^\mu\chi\bar{q}\gamma_\mu q$ or axial-vector $\bar{\chi}\gamma^\mu\gamma^5\chi\bar{q}\gamma_\mu\gamma^5q$) since, according to the assumption made, its mediator can usually be integrated out [53].

Despite of this strong assumption, this approach is actually quite useful anyway in the sense that it is able to provide us bounds on the new physics scale Λ , which can be related to the different couplings of the interaction as in Equation 2.20, where g_q and g_χ are the coupling between the mediator and the SM or DM particle, and m_{med} is the mass of the mediator.

$$\frac{1}{\Lambda^2} = \frac{g_q g_\chi}{m_{\text{med}}} \quad (2.20)$$

Additionally, direct searches experiments typically also introduce this kind of assumptions to extract constraints from their measurements, making it straightforward to compare the results obtained in both approaches. However, the transfer of momentum in the direct searches

experiments is usually of the order of a few keV as seen in Equation 2.21, while in collider experiments such as the LHC, this is of the order of $\Theta(\text{GeV-TeV})$.

$$E = \frac{m_\chi v_\chi^2}{2} \simeq 100 \text{ GeV} \cdot 10^{-6} \simeq 50 \text{ keV} \quad (2.21)$$

This means that, especially due to the increasing center of mass energy given by the LHC over the last few years, the basic EFT assumption is usually not respected and gives information about an out of reach phase space region anyway, making its usefulness quite relative in most cases. This is why more complex models need to be developed as well.

- The simplified models attempt to solve the issue related to the approximation made by the EFT approach, by increasing the level of details regarding the interaction between the dark and baryonic sectors. This is usually done by explicitly taking into account the mediator of the interaction, which can be considered of two different types in the context of this work: either scalar ϕ or pseudoscalar a (both having a spin 0), described by the Lagrangians in Equation 2.22, considering the DM candidate to be a Dirac fermion coupling to the SM through the mediator considered and under the assumption of Minimal Flavour Violation (MFV). In this equation, the sum runs over the three SM families and the parameters $y_i^f = \sqrt{2} \frac{m_i^f}{v}$ are the Yukawa couplings, much larger for the top quarks because of their mass, which will allow us to simplify the following equations [65].

$$\begin{cases} \mathcal{L}_{\text{fermion},\phi} \propto -g_\chi \phi \bar{\chi} \chi - \frac{\phi}{\sqrt{2}} \sum_i (g_u y_i^u \bar{u}_i u_i + g_d y_i^d \bar{d}_i d_i + g_l y_i^l \bar{l}_i l_i) \\ \mathcal{L}_{\text{fermion},a} \propto -ig_\chi a \bar{\chi} \gamma^5 \chi - \frac{ia}{\sqrt{2}} \sum_i (g_u y_i^u \bar{u}_i \gamma^5 u_i + g_d y_i^d \bar{d}_i \gamma^5 d_i + g_l y_i^l \bar{l}_i \gamma^5 l_i) \end{cases} \quad (2.22)$$

An important parameter in this case is the decay width of this mediator Γ_{med} , given by Equation 2.23 for either a scalar mediator ϕ or Equation 2.24 for a pseudoscalar mediator a , where the first term corresponds to the mediator decay to SM particles, the second to its decay to DM particles and the last term its possible decay to gluons.

$$\begin{cases} \Gamma_\phi = \sum_f N_C \frac{y_f^2 g_\nu^2 m_\phi}{16\pi} \left(1 - \frac{4m_f^2}{m_\phi^2}\right)^{3/2} + \frac{g_\chi^2 m_\phi}{8\pi} \left(1 - \frac{4m_f^2}{m_\phi^2}\right)^{3/2} + \frac{\alpha_S^2 g_\nu^2 m_\phi^3}{32\pi^3 \nu^2} \left| f_\phi \left(\frac{4m_t^2}{m_\phi^2} \right) \right|^2 \\ f_\phi(\tau) = \tau \left(1 + (1 - \tau) \arctan^2 \left(\frac{1}{\sqrt{\tau - 1}} \right) \right) \end{cases} \quad (2.23)$$

$$\begin{cases} \Gamma_a = \sum_f N_C \frac{y_f^2 g_\nu^2 m_a}{16\pi} \left(1 - \frac{4m_f^2}{m_a^2}\right)^{1/2} + \frac{g_\chi^2 m_a}{8\pi} \left(1 - \frac{4m_f^2}{m_a^2}\right)^{1/2} + \frac{\alpha_S^2 g_\nu^2 m_a^3}{32\pi^3 \nu^2} \left| f_a \left(\frac{4m_t^2}{m_a^2} \right) \right|^2 \\ f_a(\tau) = \tau \arctan^2 \left(\frac{1}{\sqrt{\tau - 1}} \right) \end{cases} \quad (2.24)$$

In the case of the simplified models, the minimal set of parameters describing the interaction is therefore $\{m_\chi, m_{\text{med}}, g_\chi, g_q\}$.

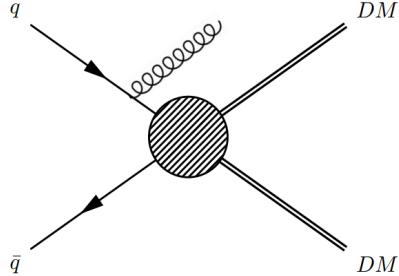

Figure 2.22: Schematic representation of a typical EFT modelization of an LHC event with an Initial State Radiation (ISR) object used to trigger the event [53].

An additional categorization of the DM production models can be done, by separating the so-called s-channel and t-channel models, as shown in Figure 2.23. In the first case, the most common one in collider searches, the mediator between the SM and DM is assumed to be a boson, and usually decays directly into a pair of DM particles. On the other hand, in the t-channel models, the mediator couples to one quark and one DM particle, with a colored exchange particle required.

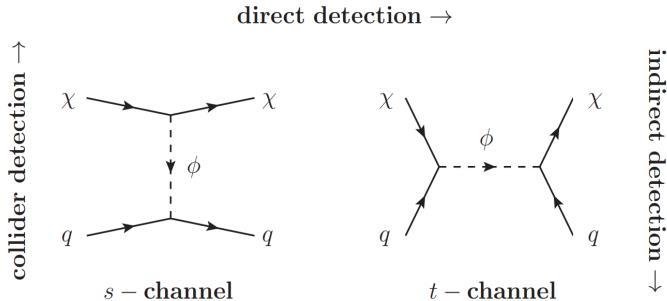

Figure 2.23: Schematic representation of a typical collider DM production through s-channel and t-channel processes [66].

In this work, simplified models with either scalar or pseudoscalar mediators will always be considered because of their relative simplicity and the lack of strong assumptions behind them. We will now study in particular the production and the search for DM within the LHC.

2.6 DM production at the LHC

The Large Hadron Collider (LHC), colliding protons at a center of mass energy of 13 TeV, is actually a perfect machine to study such processes, because of the expected range of masses (100 GeV to 1 TeV) for the best DM candidates, as discussed in Section 2.3. However, because of the weak

interactions of such particles, they are not expected to interact at all with the detector, which will then basically search for missing transverse energy along with a SM particle triggering the event.

Several major categories of DM searches exist at the LHC, performed mainly by the CMS and ATLAS collaborations, depending on the strategy applied for such searches:

- First of all are the so-called **mono-X searches**, where X stands for a detectable SM particle used to trigger the event while the DM mediator usually decays into a pair of particles escaping the detector, leaving behind some Missing Transverse Energy (MET), a key variable to all these searches, as shown in Figure 2.24. Depending on the nature of the X particle, several searches can be performed: we can for example mention the mono- γ [67, 68] or mono-jet [69, 70] 13 TeV searches performed by the ATLAS and CMS collaborations.

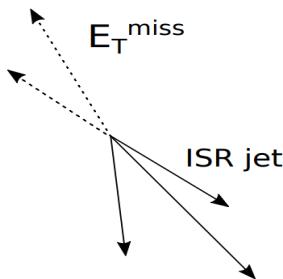

Figure 2.24: Schematic representation of a typical mono-X event, with an ISR jet in this case going back-to-back with some MET [53].

Additionally, if the DM mass is high enough, a coupling to the Higgs boson is also possible, or an eventual decay of the Higgs itself to a couple of DM particles $H \rightarrow \chi\bar{\chi}$ is kinematically not impossible. This channel, known as the mono-Higgs searches is sensitive to all the decays of the Higgs, even though the searches excluding most of the phase spaces are performed using the $H \rightarrow b\bar{b}$ and $H \rightarrow \gamma\gamma$ decays, mainly because of their branching ratios [71, 72].

- Then, we can find the searches for DM production in **association with heavy quark(s)**. This particular search for DM produced in association with one or two quark pairs can be typically quoted within this category and will be detailed in the next section, but other analyses such as the one probing the $b\bar{b} + \text{DM}$ to its different final states depending on the decay of the bottom quark also belongs to this group, at 8 or 13 TeV [13, 17].

These searches have to combine the discriminant power of several variables to separate the signal from the backgrounds, since the MET distribution on its own is usually not enough, but they present the advantage of being favored by the higher Yukawa coupling to more massive particles implied by the MFV assumption.

- **Dijet searches** are also an important part of the work being performed using the LHC data, and actually provide the best exclusion limits for most the spin-1 mediated models considered (up to a few TeV for typical coupling choices!) [73, 74]. In this case, the sensitivity is obtained

by searching for either narrow or large resonances on the exponentially falling QCD background, while the other searches were mostly dedicated in searching for bumps in the MET spectrum.

- **Supersymmetric searches**, such as SUSY searches, can also be performed to search for DM which would solve the hierarchy problem while giving us perfect DM candidates such as the neutralino χ , the lightest stable supersymmetric particle, obtained in many of the MSSM theories, having an hypothetical mass below the TeV scale [75].
- The **Higgs portal** to the dark sector is another interesting strategy. In some specific cases, when considering spin-0 mediated interactions between the dark and baryonic sectors, the Higgs could be considered as the mediator of the interaction as well, which only require a minimal modification of the SM Lagrangian. It is then necessary to study the different Higgs production modes, such as the gluon fusion and Vector Boson Fusion (VBF) mechanisms, to search for an eventual invisible decay of the Higgs into a couple of DM particles, assuming that its mass is lower than ~ 62.5 GeV, $m_H/2$ [76].
- Finally, and this is quite new, **long-lived searches** can also be performed. These are interested because they can extend the current searches performed to also consider the eventual creation of long-lived particles which would decay a few centimeters further than the primary vertex of the proton-proton collision [77]. Typical SM signatures do not usually include such events, making this channel relatively background-free, even though the reconstruction of the different objects is much harder in this case.

All the results obtained the different searches performed by the CMS collaboration using the full 2016 dataset can be summarized in Figure 2.25 for spin-0 mediators and in Figure 2.26 when considering spin-1 mediators.

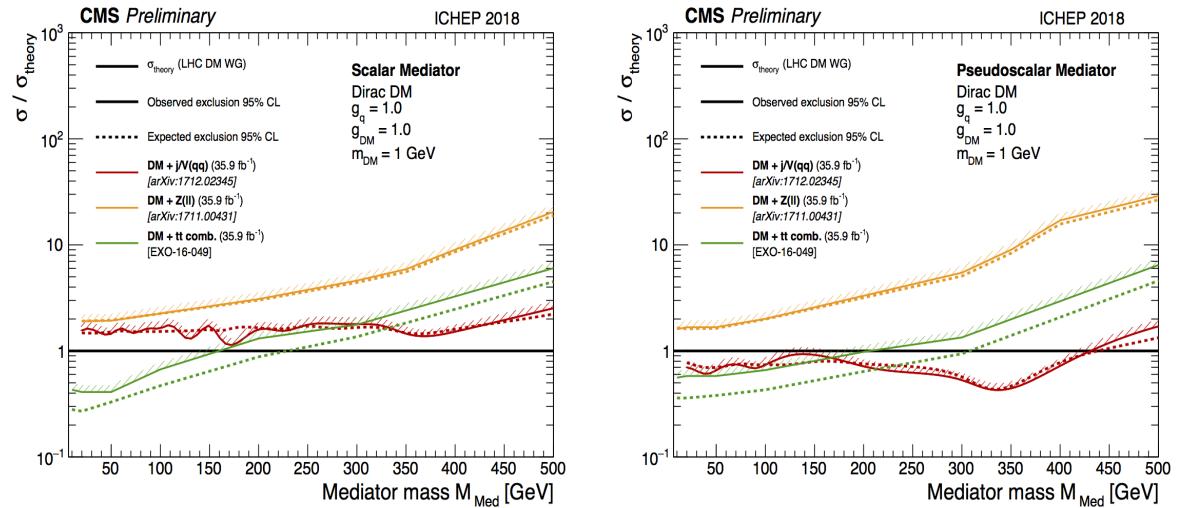

Figure 2.25: Observed and expected 95% exclusion limits obtained by different searches of the CMS collaboration as a function the spin-0 scalar (on the left) or pseudoscalar (on the right) mediator.

These results have also been compared to the results obtained by several direct detection experiments in Figure 2.27, considering both the Spin Dependent (SD) and Spin Independent (SI) cases, as

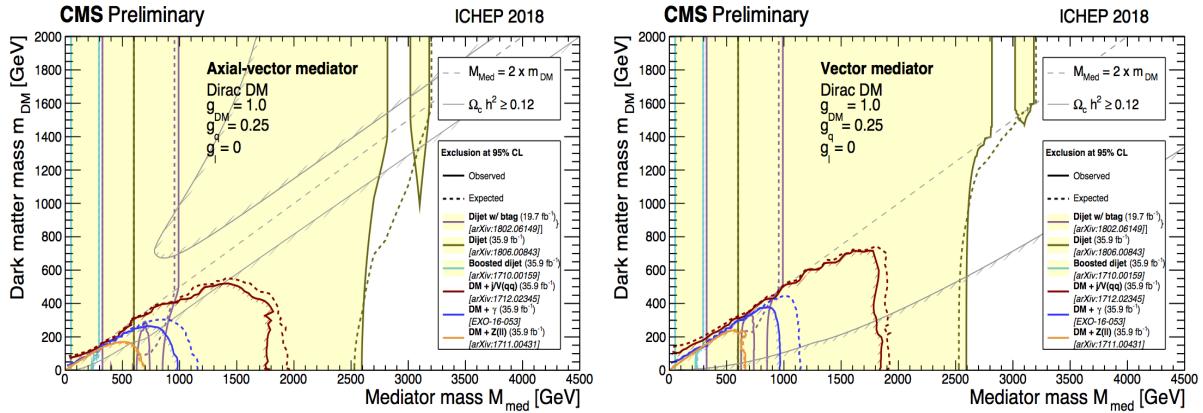

Figure 2.26: Observed and expected 95% exclusion limits obtained by different searches of the CMS collaboration as a function the spin-1 mediator, considering an axial-vector (on the left) and axial (on the right) interaction.

explained in Section 2.5.1.

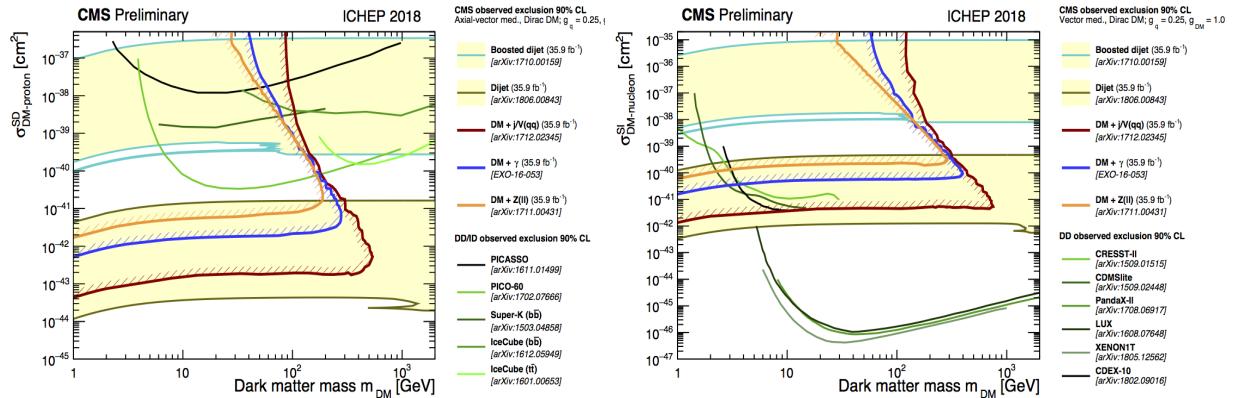

Figure 2.27: CMS 90% exclusion limits compared to the most famous direct detection experiments for the SD (on the left) and SI (on the right) scenarios, obtained using similar couplings.

This particular analysis and our signal of interest, the search for DM production in addition with a single or a pair of top quarks falls into the second category and will now be detailed. It is already important to note that this analysis has been performed considering the DM candidate to be a 1 GeV Dirac fermion with all the couplings equal and set to 1, as recommended by the Dark Matter Working Group (DMWG) [78].

2.6.1 The single top production channel

The first kind of signal considered in this analysis is the production of DM in association with a single top quark, known as t/\bar{t} +DM analysis. This process is expected to be mediated by a spin-0 mediator, either scalar or pseudoscalar, and is associated with a light quark and a W boson (the mono-top analysis is dealing with the case where a single top is created without any additional particle).

Three different Feynman diagrams can be associated to this particular analysis depending on the

model considered, as shown in Figure 2.28.

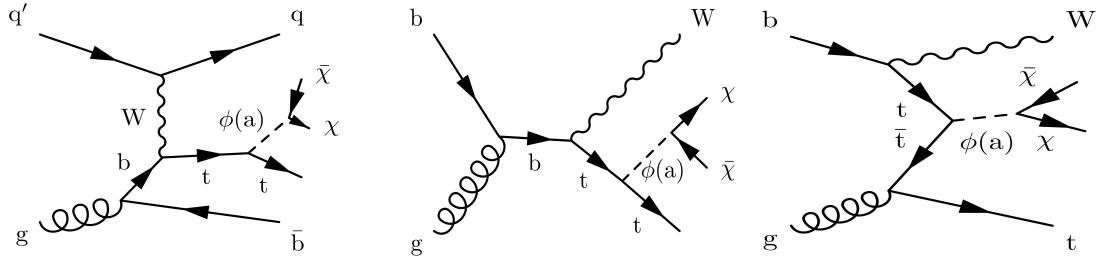

Figure 2.28: Feynman diagrams involving the production of DM with a single top quark with its associated t-channel W boson (on the left), or tW (on the center and on the right) production.

As discussed previously, the top quark will be dynamically favored due to its high mass and therefore high Yukawa coupling, but however this has a negative effect as well, since the lifetime of this quark is extremely low, of the order of 10^{-15} s [79]. This means that this particle usually decays before being able to form hadrons and before reaching the CMS detector, so we can only detect the products of its decay, not the top quark itself. In almost 100% of the cases, the top actually decays into a bottom quark and a W boson, which decays itself before being detected into quarks and/or leptons. Even though this will be detailed in Chapter 6, we can already conclude that the typical final state of such signature is therefore made out of MET coming from the DM, one b-tagged jet along with one or two W bosons, seen as a combination of jets and leptons, depending on the channel considered.

2.6.2 The $t\bar{t}$ production channel

The $t\bar{t}$ +DM analysis is really similar, except that in this case, we have two top quarks in the final state, as represented in Figure 2.29.

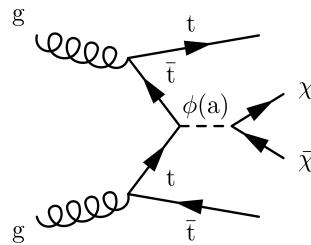

Figure 2.29: Schematic representation of a typical $t\bar{t}$ +DM event.

The final state expected by such an event is therefore made of two b-tagged jets, along with two W bosons and some MET coming from the pair of DM particles as well. In this case as well, both scalar ϕ and pseudoscalar a mediators will be considered as well, with a mass range from 10 to 500 GeV.

2.6.3 The dilepton final state

As previously explained, most of the models considered will produce exactly two W bosons, which are not stable long enough and therefore decay before reaching the detector, meaning that we cannot directly detect such bosons. However, we can detect the results of the decays of these W, since they can decay either to hadrons ($67.6 \pm 0.27\%$ branching ratio) or to a lepton and a neutrino, giving us an additional contribution of MET ($10.8 \pm 0.09\%$) [79].

This means that this kind of analyses featuring two W bosons in the final state can focus on different channels: either completely hadronic (if both the W decay into quarks), semileptonic or dileptonic (when both the W decay into two neutrinos and two leptons of opposite charge).

Given the Branching Ratio (BR) of the W decay, it is easy to see that the dileptonic channel, which will be the focus of this work, is clearly not favored statistically. However, it is interesting anyway to study this kind of decay because this channel typically features less backgrounds than other channels, resulting in a better signal isolation, and because leptons can usually be reconstructed in a better way than jets (cf. Chapter 4), resulting in lower uncertainties and in improved limits.

2.7 Previous relevant results

This analysis being performed at a center of mass energy $\sqrt{s} = 13$ TeV, only the most relevant results to this particular energy and previously obtained by both the CMS and ATLAS collaborations of CERN will be quoted here.

First of all, the **ATLAS collaboration** published interesting results at this center of mass energy, considering an integrated luminosity of 13.3 fb^{-1} , and obtained the corresponding exclusion limits at the 95% CL, considering the $t\bar{t}+\text{DM}$ model and both scalar and pseudoscalar spin-0 mediators for the interaction, as shown in Figure 2.30. In this case, and for the couplings considered, an exclusion up to ~ 375 GeV has been achieved.

Considering the full 2016 dataset of 36.1 fb^{-1} , similar results have been obtained, as shown in Figure 2.31. In this case, and for lower coupling values, an exclusion up to around 100 GeV has been obtained considering scalar and pseudoscalar mediators.

The **CMS collaboration** published in 2018 a similar analysis, but using only the 35.9 fb^{-1} of data collected during the year 2016. This analysis combined the three different final states possible (hadronic, semileptonic and dileptonic) and computed the limits on the signal strength for different mediator and dark matter masses, considering both scalar and pseudoscalar mediators [19]. The results obtained can be found in Figure 2.32.

Last year, a combination of the $t/\bar{t}+\text{DM}$ and $t\bar{t}+\text{DM}$ analyses has also been published [20], combining this time only the hadronic and semileptonic channels of both analyses. The limits obtained in this

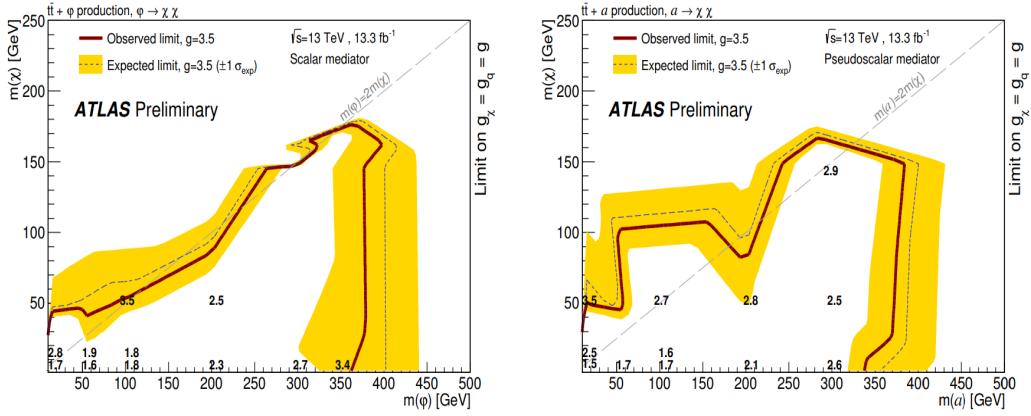

Figure 2.30: Limits on the mass on the DM and mediator masses obtained by ATLAS using 13.3 fb^{-1} of 13 TeV data, considering scalar (on the left) and pseudoscalar (on the right) mediators [14].

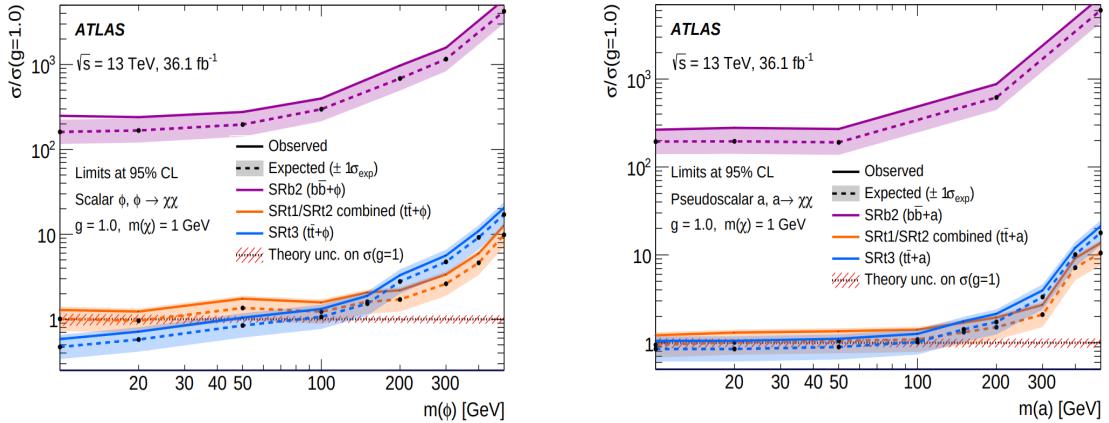

Figure 2.31: Exclusion limits at the 95% CL obtained by ATLAS considering scalar (on the left) and pseudoscalar (on the right) mediators, for a DM mass of 1 GeV [17]

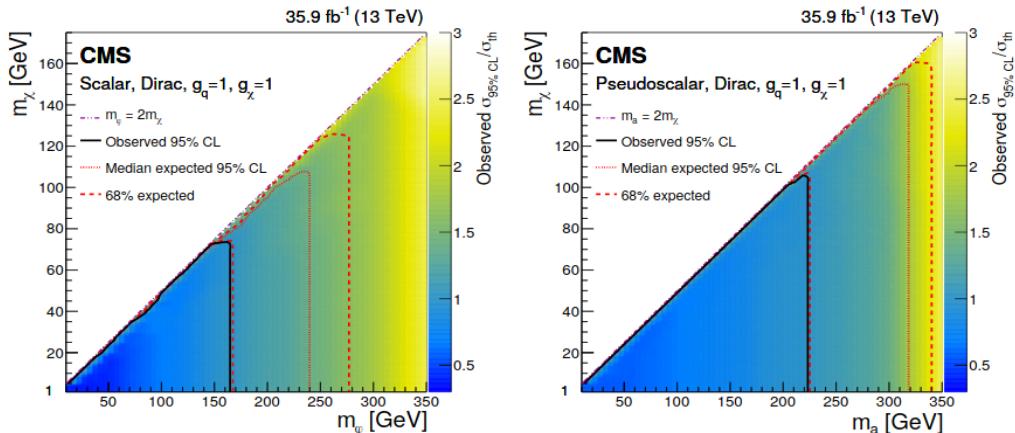

Figure 2.32: 95% CL exclusion plots on the signal strength computed as a function of the mediator and DM masses obtained by CMS considering a scalar (on the left) and a pseudoscalar (on the right) mediator for the interaction [19].

case are represented in Figure 2.33, where the limits obtained by each analysis on their own along with the results of the combination, leading to a factor 2 improvement of the limits obtained, have been represented.

This combination managed to exclude the production of scalar mediators up to 290 GeV and pseudoscalar mediators up to 300 GeV, at the 95% CL for the couplings considered. This combined analysis actually lead to the most stringent exclusion limits of the LHC on the production of DM through these categories of spin-0 mediators.

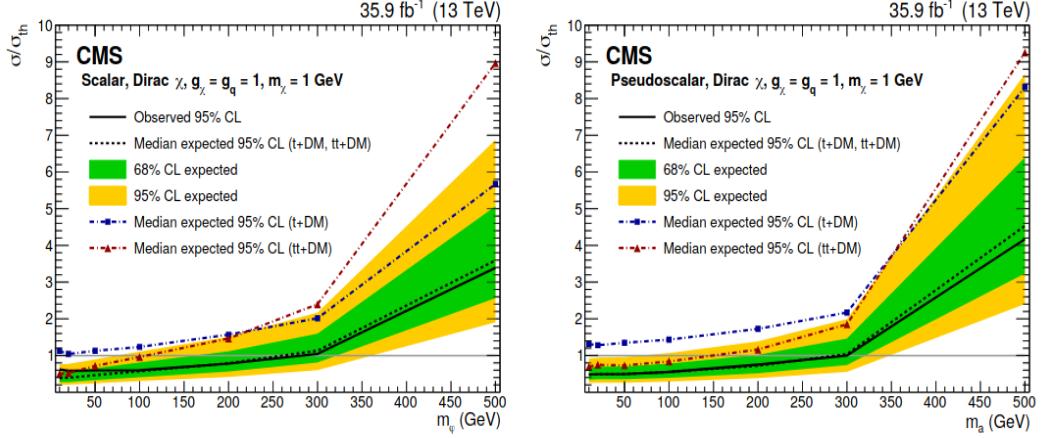

Figure 2.33: Expected and observed 95% CL limits on the DM production cross sections shown considering scalar (on the left) and pseudoscalar (on the right) mediators for the interaction [20].

Chapter 3

The experimental setup

The data analyzed throughout this work is the result of the proton-proton collisions at a center of mass energy of 13 TeV provided by the Large Hadron Collider (LHC). It is therefore extremely important to describe this particle accelerator and to detail its main characteristics in order to understand better the origin of our data, as will be done in Section 3.1.

This kind of collisions at high energy typically produces hundreds or even thousands of new particles that we then need to identify, and whose exact properties, such as their momentum or their electric charge, need to be measured. This is done by using the Compact Muon Solenoid (CMS) detector, an incredibly sophisticated detector, result of the work of thousands of scientists and made of several different layers, which will be described in Section 3.2 of this chapter.

3.1 The LHC accelerator

The Large Hadron Collider (LHC) is a superconducting particle accelerator able to accelerate protons and heavy lead ions up to a velocity close to the speed of light. Planned since the end of the 20th century, this accelerator, a 27 kilometers ring put 100 meters underground to remove part of the contamination due to the cosmic rays and located at CERN, at the border between Switzerland and France and, has now been running for 10 years. The LHC is the result of the collaboration between thousands of scientists of more than 100 different nationalities and its main objective was first of all to either infer or confirm the possible existence of the Higgs boson, theoretically predicted in the 1960s [1, 2] but never observed in any experiment. The discovery of the Higgs boson, announced at CERN on the 4th of July 2012 [3, 4], was then an incredible achievement of the accelerator, after only two years of operation.

Now that the Higgs boson has been discovered, the priority of the LHC shifted a bit. Even though many different teams are still studying this particle in order to determine precisely its most fundamental properties such as its mass or its spin, many groups of scientists are now involved in different kind of BSM physics since the LHC, whose center of mass energy has kept increasing over the years, allow us to reach a level of energy never reached before, and would therefore potentially allow us

to probe new parts of the phase space, searching for eventual hints of new physics. These kind of searches of course include the search for eventual DM production as the one performed in this work.

Let's now start with a global description of the general design of this particle accelerator in Section 3.1.1 before describing in more details the key parameters allowing us to evaluate its actual performances in Section 3.1.2.

3.1.1 The LHC in a nutshell

The LHC is an underground particle accelerator built in the same 27 kilometers tunnel where the Large Electron Positron collider (LEP) was previously used. This machine is accelerating two beams made out of billions of protons or lead ions in each direction and is mostly made out of more than 4000 superconducting magnets, in majority dipoles and quadrupoles, allowing respectively to curve the beam to maintain a nominal circular trajectory and to focus it, by compensating its natural dispersion due to the repulsion of the protons making up these beams. A dedicated small section of the accelerator is then made out of 16 radio-frequency cavities synchronized in such a way that these protons always face a negative electric charge, which is used as the driving process of the actual acceleration of such particles.

Once the nominal center of mass energy $\sqrt{s} = 13$ TeV reached (this concept will be described in Subsection 3.1.2), the protons are then smashed together in four different places on the LHC, where the four detectors (ATLAS, CMS, A Large Ion Collider Experiment (ALICE) and LHCb) have been placed in order to study the collisions. Both ATLAS and CMS are general detectors, able to study exotic processes such as the production of DM and to make precision measurements on SM physics as well (the decision to build two separate detectors was made in order to introduce some redundancy and to check the results). ALICE on the other hand, is mostly dedicated to the study of heavy ions collisions that happen $\sim 10\%$ of the time in order to study in particular a specific state of matter, called the quark-gluon plasma [80]. Finally, LHCb has been designed to study in particular the CP violation phenomena, which could be the sign of some new physics [81].

It is important to note at this point that the LHC is not a standalone accelerator in the sense that protons enter the LHC with a velocity already close to the speed of light. In order to reach such input energies (~ 450 GeV), previous smaller accelerators of CERN are still used today: first of all, the protons, extracted from a bottle of ordinary hydrogen, are injected into the LINAC 2, a linear accelerator, before being transferred to the Proton Synchrotron (PS), the Super Proton Synchrotron (SPS) and finally the LHC itself (all this chain of acceleration can be found in Figure 3.1).

During this phase of acceleration, the beam is separated in a series of 2808 bunches of protons nominally separated by 25ns (giving a collision rate of 40 MHz), so that the experiments have the time to record the collision, clean the detectors and get ready for the next bunch crossing, coming just a few nanoseconds later. Each time one bunch crossing happens, around 35 collisions of protons happen at once: this phenomena, usually referred to as Pile Up (PU), has to be taken into account as well and will be described in the next section.

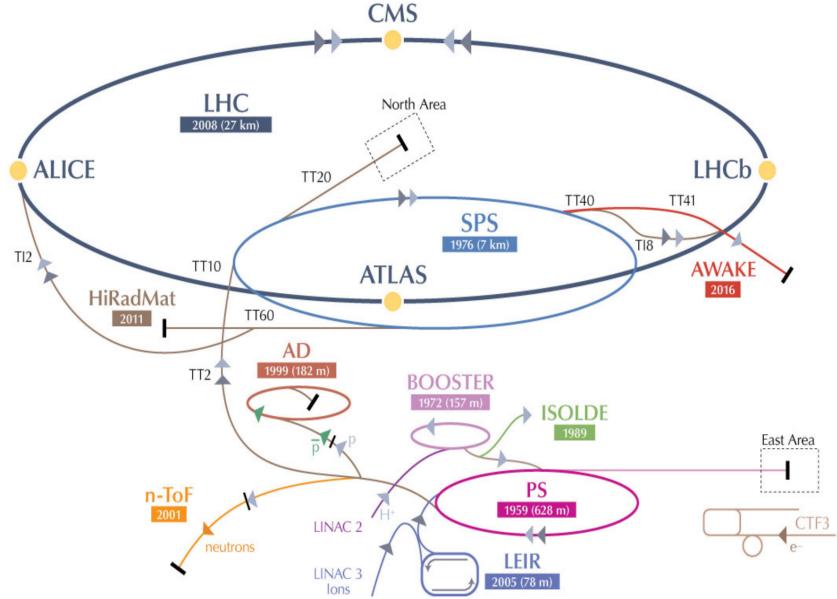

Figure 3.1: LHC injection chain and experiments performed at CERN [82].

As previously stated, the amount of data collected is a crucial parameter for many analyses, meaning that the LHC would ideally need to run 24 hours a day, 365 days per year in order to maximize the data taking. However, this is not possible, as setting up a beam takes time and we cannot keep it running at maximal energy forever in the machine, so in ideal conditions around 20 hours of data taking a day are expected. The LHC is then running around 9 months per year, being usually stopped during the winter for maintenance operations, and the data taking periods are defined into Runs of a few years, after which the accelerator is usually stopped for a longer period of time, in order to also perform upgrade operations of the machine. The data analyzed in this work corresponds to the second phase of the Run II of operation, from 2016 to 2018, while the Run III is now expected to start in the Spring of 2021.

3.1.2 LHC key parameters

Center of mass energy

The center of mass energy is defined as a Lorentz invariant quantity under longitudinal boosts resulting of the collisions of two protons (defined as E_1, \vec{p}_1, m_1 and E_2, \vec{p}_2, m_2) with a θ angle, as developed in Equation 3.1. It is a key variable of the LHC since the phase space of particles that can be explored directly depend on this value.

$$\sqrt{s} = \sqrt{(m_1)^2 + (m_2)^2 + 2(E_1 E_2 - 2|\vec{p}_1| |\vec{p}_2| \cos(\theta))} = 13 \text{ TeV} \quad (3.1)$$

The LHC started its operation in 2008 running at an energy of 8 TeV and kept this level of energy during the full Run I of operation. In 2015, for the Run II of data taking, the energy was increased until reaching 13 TeV (2 times 6.5 TeV for each beam) and an expected value of 14 TeV, the nominal energy for which the LHC was originally built, is expected to be reached in the near future.

Luminosity

The luminosity is another extremely important variable for the operation of the LHC since, as a rule of thumb, it gives an indication on the number of collisions per second given by the accelerator. Increasing this parameter is extremely important in order to collect as much data as possible, in order to be able to isolate processes having a low production cross section and therefore an extremely low probability of apparition when colliding two protons.

Mathematically, we can first of all define in Equation 3.2 the rate R of production (in number of events per second) of any given process using its cross section σ , equivalent to its production probability, and the instantaneous luminosity \mathcal{L} . From this rate can be extracted easily the number of expected interactions N in a certain amount of time T as well.

$$\begin{cases} R = \mathcal{L} \cdot \sigma \\ N(T) = \sigma \int_0^T \mathcal{L}(t) dt = \sigma L \end{cases} \quad (3.2)$$

This instantaneous luminosity we just introduced \mathcal{L} can be defined using Equation 3.3, assuming that the beams have a Gaussian profile, while the integrated luminosity L can be defined by simply integrating the instantaneous luminosity over time $L = \int \mathcal{L} dt$ [83].

$$\mathcal{L} = \frac{\gamma f_{\text{rev}} k_B N_p^2}{4\pi \epsilon_n \beta^*} R \quad \text{where } R = \frac{1}{\sqrt{1 + \frac{\theta_C \sigma_z}{2\sigma}}} \quad (3.3)$$

In this last equation, the following properties of the accelerator have been introduced, giving the LHC a nominal instantaneous luminosity $\mathcal{L} = 1 \cdot 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$:

- γ is the usual relativistic Lorentz factor (for the LHC, when protons go at their maximum velocity of 99.999991% of the speed of light, $\gamma = 7460$)
- f_{rev} is the frequency of revolution (11.2 kHz)
- k_B is the number of proton bunches per beam (2808 for a 25 ns bunch spacing)
- N_p is the number of protons per bunch ($1.15 \cdot 10^{11}$ protons)
- ϵ_n is the transverse normalized emittance ($3.75 \mu\text{m}$)
- β^* is the betatron function at the interaction point (0.55 m)

- R is the geometrical factor accounting for the fact that the collisions do not happen exactly head-on, therefore reducing the effective luminosity, expressed from the full crossing angle between colliding beam θ_C ($285 \mu\text{rad}$), and σ, σ_z , the transverse and longitudinal r.m.s. sizes (respectively $16.7 \mu\text{m}$ and 7.55 cm).

As previously stated, increasing the luminosity of the LHC is always something interesting in order to produce processes having a low production cross-section, and we can then see that many different parameters can be tweaked in order to achieve the highest possible instantaneous luminosity, such as the number of protons per bunch, the number of bunches per beam or the beam crossing angle at the interaction point. New crab cavities will probably be installed during the next Long Shutdown (LS) of the LHC in order to increase the value of the geometrical factor R and the instantaneous luminosity by a factor ~ 10 (HL-LHC project [84]).

The total integrated luminosity taken by the LHC during its different years of operation has been summarized in Figure 3.2. The final datasets available that will be analyzed in this work have an integrated luminosity of 35.9 fb^{-1} (2016), 41.5 fb^{-1} and 59.7 fb^{-1} (2018), resulting in a total dataset of 137 fb^{-1} recorded during the Run II of operation. This typically means that we expect to produce around 137 events of any process whose cross section of production would be equal to 1 fb .

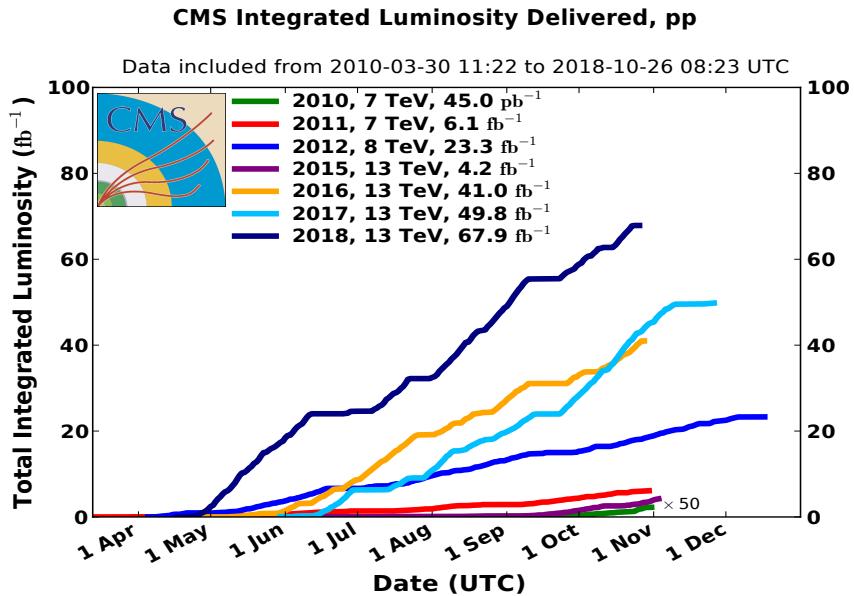

Figure 3.2: Integrated luminosity collected by CMS over its different years of operation so far.

Pile Up (PU)

The last key parameter of the LHC discussed here is the Pile Up (PU). Usually, because of the high density of protons within the beams, a bunch crossing in a experiment produces around 35 collisions protons collisions, as seen in Figure 3.3, of which only the most interesting one will be kept, defining the Primary Vertex (PV), while the other vertices are usually referred to as the PU. The tracker

of CMS, which will be introduced in the next section, therefore needs to be able to reconstruct all these events in order to define the PV of the interaction.

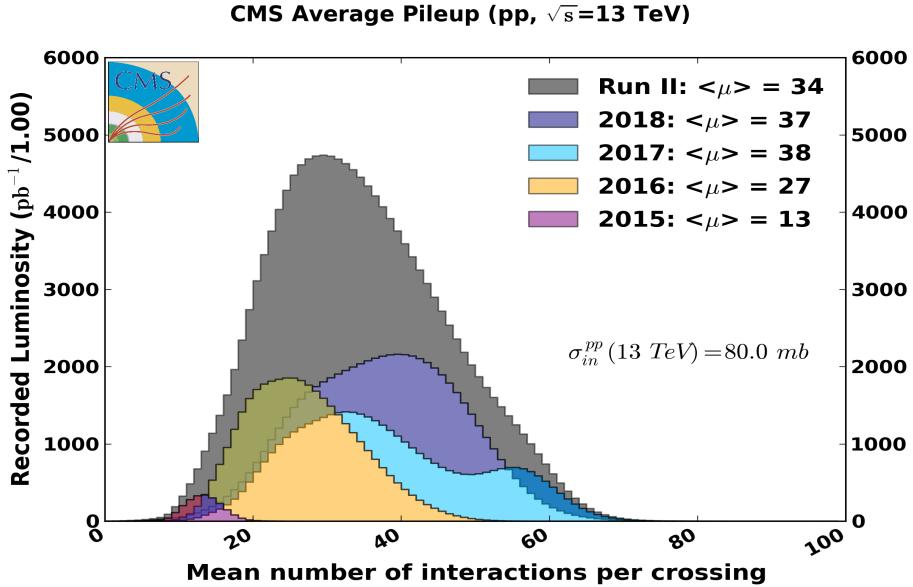

Figure 3.3: Mean PU distribution and luminosity recorded by CMS over the different years of operation of the LHC.

3.2 The CMS detector

The Compact Muon Solenoid (CMS) is one of the two general purpose detectors installed at the access point 5 of the LHC. Its main purposes were to discover the Higgs boson, make precision measurement of most of the SM processes and to try and discover BSM physics, such as the possible existence of DM. It has been carefully designed by hundreds of different physicists and engineers in order to be as hermetic as possible, covering all the possible angles around the beam pipe, the point of origin of all the collisions provided by the LHC, and is therefore made of three main sections: the cylindrical barrel at the center, and the two endcaps, one on each side of the detector. CMS was lowered into the experimental cavern underground after being built on the surface in 14 different moving pieces, a flexible design allowing to access its inner parts, by opening and closing the detector when needed.

As we can see in Figure 3.4, CMS, which weights 14.000 tons and has a diameter of 15 meters and a length of 28.7 meters, is made out of different layers, corresponding to different sub-detectors, each able to provide different kind of information about the hundreds of particles created by each collision [85]. These sub-detectors will be described in details in the following sections, but they have all been designed in order to make the reconstruction of the different events as efficient, fast and precise as possible and need to be quite cheap but still extremely resistant to the radiation produced.

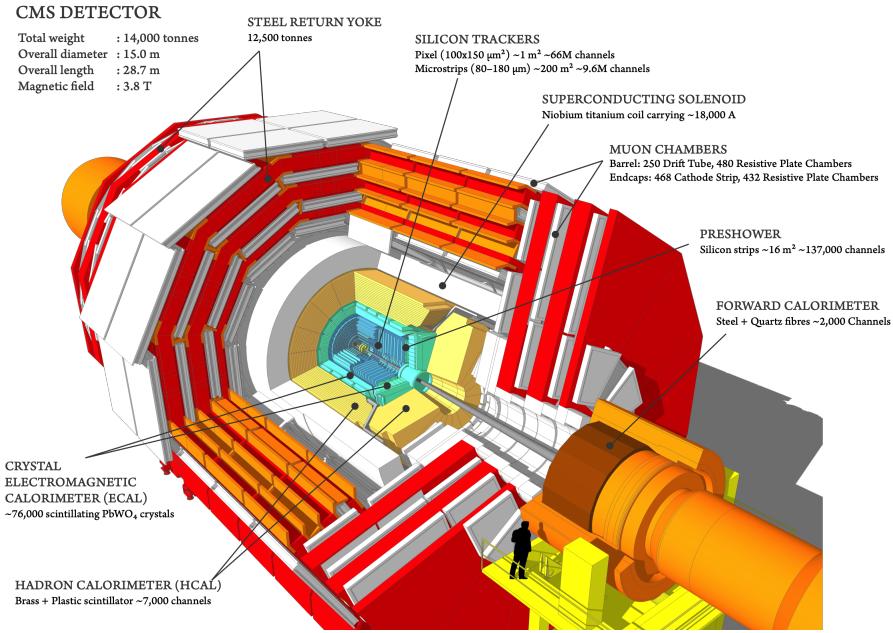

Figure 3.4: Schematic representation of the CMS detector, along with all its sub-detectors and main characteristics.

The inner part of the CMS detector is the so-called tracker, a device made out of silicon pixels and strips, described in Section 3.2.1 and responsible for the precise reconstruction of all the charged particles coming from the different interaction vertices. A bit further, we can find the Electromagnetic Calorimeter (ECAL), made out of thousands of crystals as described in Section 3.2.2 and used to precisely measure the energy of particles able to interact electromagnetically by producing an electromagnetic shower that can be detected. Then comes the Hadronic Calorimeter (HCAL), described in Section 3.2.3 and whose main purpose is to identify and measure the main properties of the hadrons produced in the collisions by producing hadronic showers.

The CMS name partly comes from its central piece, a huge superconducting solenoid described in Section 3.2.4 and able to produce a 3.8 T magnetic field in the detector, with a magnetic flux density increased even more by the addition of the steel return yoke layers (red parts in Figure 3.4). This magnetic field is essential in the sense that it is able to deflect the charged particles which have been produced via the Lorentz interaction, therefore giving us an additional way to measure their charge and energy from the measurement of the curvature of the induced binding.

Finally, on the outside of the detector can be found the complete muon system and particularly performing in CMS. This sub-detector is currently made out of three main sub-systems (the Drift tubes (DTs), Cathode Strip Chambers (CSCs) and Resistive Plate Chambers (RPCs)), as explained in Section 3.2.5, and is responsible for the identification and measurement of the momentum of the muons produced by the collisions.

Before starting with the description of all these sub-detectors, it is important to detail the coordinate system typically used within the CMS collaboration. As a convention, it has been decided to use

a right-handed Cartesian coordinate system with the origin defined as the Primary Vertex (PV), and with an x-axis pointing towards the center of the ring, an y-axis pointing upwards and a z-axis pointing towards the Jura mountains (along the counterclockwise beam direction), as represented in Figure 3.5.

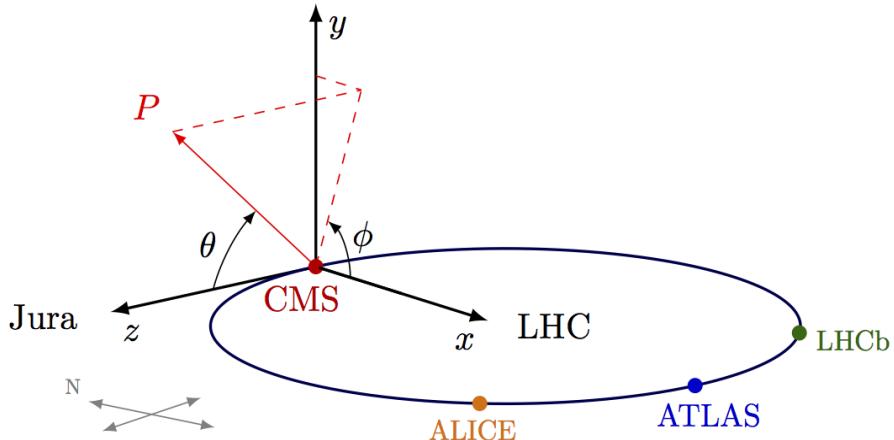

Figure 3.5: Schematic representation of the CMS coordinate system used by convention.

The θ and ϕ angles are then defined as the angles between the z and y axes and the x and y axes respectively, and the pseudorapidity η , a Lorentz invariant quantity under longitudinal boosts quite often used in the different analyses, is defined using Equation 3.4.

$$\eta = -\log \left(\tan \left(\frac{\theta}{2} \right) \right) \quad (3.4)$$

3.2.1 Tracker

The tracker is the inner-part of the CMS detector, is 5.4 meters long and has a diameter of 2.5 meters. Its main purpose is the reconstruction of the trajectories of charged particles issued from the primary and secondary interaction vertices in a quick and precise way, in order to identify them and measure their individual momentum.

Many challenges were faced when designing such detector, mainly because of the hard conditions provided by the LHC. First of all, at its nominal instantaneous luminosity, an average of 1000 particles are created after each bunch crossing, every 25 ns. The tracking system then needs to read all its channels extremely fast in order to be ready for the next bunch crossing. However, this fast electronics then needs some cooling to work optimally, which would in return increase the size of the tracker and therefore increase the interactions between the detector and the particles created (by multiple scattering, bremsstrahlung, photon conversion and nuclear interactions). This is of course something we definitely want to avoid, so a compromise has to be found between the velocity and size of the tracker. Finally, this device needs to be resistant to the extreme radiation environment for its expected lifetime of at least 10 years.

This device is then made out of silicon pixels and strips mainly because of the granularity, reading velocity and radiation hardness offered by such material. It has been set up on several different layers disposed in such a way to make the detector as hermetic as possible, as shown in Figure 3.6. A charged particle crossing the tracker will then leave a hit each times it crosses one of the silicon sensor, from which the track of the particle can be reconstructed using performing reconstruction algorithms that will be detailed in Chapter 4.

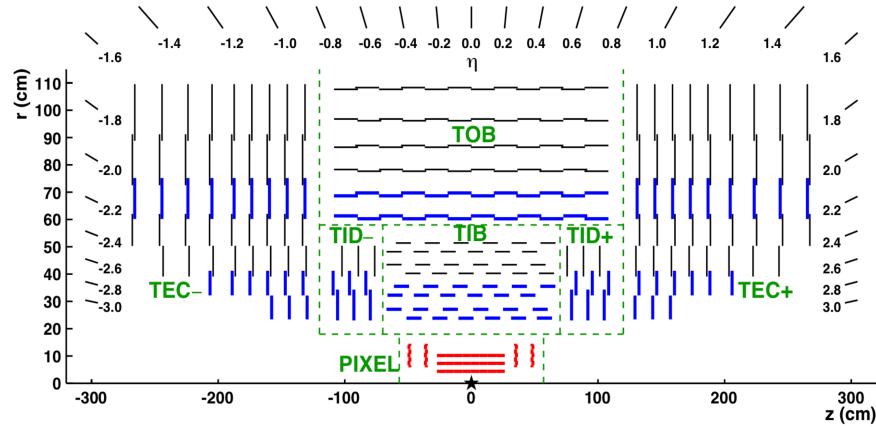

Figure 3.6: Schematic representation of the CMS tracker, for different pseudorapidity values and along the z-axis [86].

The presence of the magnetic field due to the solenoid can then help us estimate the momentum of the particle, since the Lorentz force $\vec{v} \times \vec{B}$ applied on such particle will introduce a deviation directly proportional to its momentum. The radius of curvature of particles with a high momentum (> 100 GeV) is really large, but the density of pixels and the algorithm can still manage to estimate the momentum of such particles, even though the uncertainty associated will then be greater.

In particular, the tracker is made out of two distinct parts: the smaller and inner pixel detector and the larger silicon strip detector:

- The **pixel detector** is made out of three barrel pixel layers and two endcap disks for hermeticity (located at $r = 4.4, 7.3$ and 10.2 cm of the PV), one on each side. In total, more than 60 millions pixels make up this detector, covering an area corresponding to $\sim 1\text{ m}^2$.
- The **silicon strip detector** on the other hand is composed of three different sub-systems, as seen in Figure 3.6 and covers a total area of $\sim 200\text{ m}^2$. First of all, the Tracker Inner Barrel and Disks (TIB/TBD) adds an additional 4 barrel layers and 3 endcap disks to the tracker system up to a distance $r = 55$ cm to the PV of the interaction using silicon micro-strip sensors parallel in the barrel and perpendicular beam axis in both endcaps. Then, the Tracker Outer Barrel (TOB) surrounds this first layer. Having an outer radius of 166 cm and going up to 118 cm along the z-axis, it adds 6 layers to the inner tracking system. Finally, the Tracker EndCaps (TECs) are made out of 9 disks and complete the measurement of particles emitted along the z-axis and having a high pseudorapidity η .

The CMS tracker is extremely performing: we can see in Figure 3.7 that muons are indeed reconstructed with an efficiency higher than 99% for most of the pseudorapidity spectrum, even though we can observe that this efficiency drops at high η values, mainly because of the reduced coverage provided by the pixel forward disks. The interactions between the hadrons and the tracking system is also a bit higher, which result in a lower reconstruction efficiency for such particles.

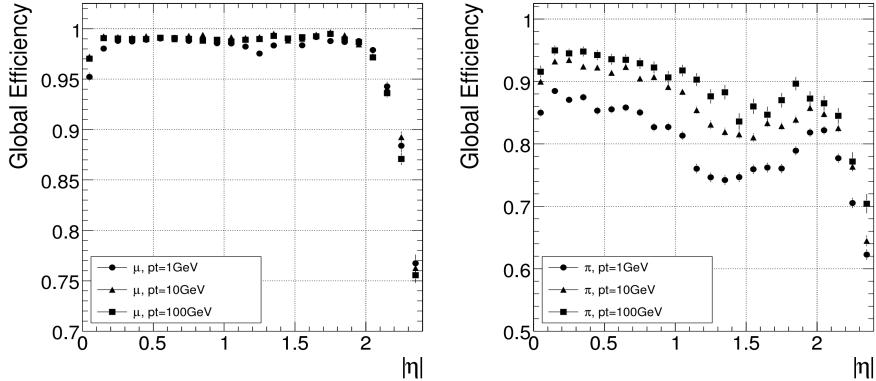

Figure 3.7: Tracker reconstruction efficiency of muons (on the left) and pions (on the right) for different pseudorapidities and particle momenta (1, 10 and 100 GeV) [85].

3.2.2 Electromagnetic Calorimeter (ECAL)

The Electromagnetic Calorimeter (ECAL) of CMS is an homogeneous detector surrounding the tracker that gives information about the energy of electrons and photons, both being able to interact electromagnetically with its crystals. The ECAL can also be divided into several sections: first of all, at pseudorapidities $|\eta| < 1.479$ is found the barrel part of the ECAL (EB), made out of 61 200 lead tungstate (PbWO_4) crystals, located at a radius of 1.29 meters of the beam pipe. Then, two endcaps, each made out of 7 324 of those crystals, complete the coverage of the detector up to $|\eta| < 3$, as shown in Figure 3.8.

Its principle of action is simple and based on electromagnetic showers: when a particle such as an electron or a photon enters the ECAL, it will start to interact in different ways: photons will mainly produce pairs of electrons and anti-electrons, while the electrons themselves tend to emit additional photons by bremsstrahlung effect. This results in a chain reaction during which the incident particle will give most of its energy to the detector itself, energy measurable using photodetectors and photomultipliers. This effect is known as an electromagnetic shower, is represented in Figure 3.9 and is usually characterized using the so-called radiation length X_0 , the mean distance over which a high-energy electron loses all but 1/e of its energy, then determining the total length of interaction of a particle in the ECAL.

The high density, short radiation length and low scintillation decay time (smaller than the bunch spacing of 25 ns) of the PbWO_4 crystals therefore makes them perfect candidates towards a compact ECAL in CMS. These crystals do have some drawbacks as well: their relative fragility when it comes

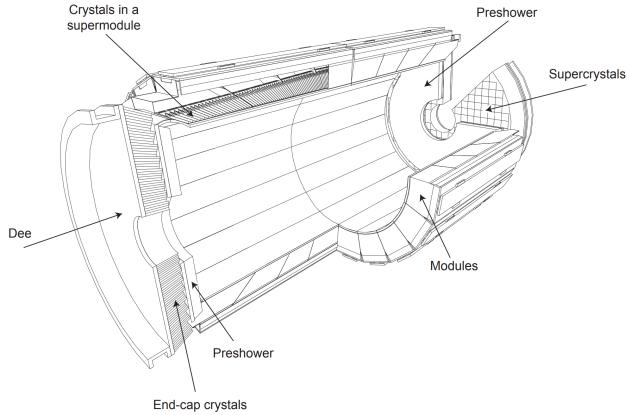

Figure 3.8: Schematic representation of the CMS ECAL [85].

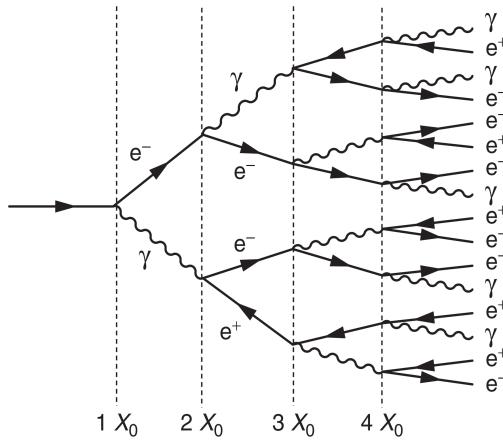

Figure 3.9: Schematic representation of a typical electromagnetic shower and the radiation length X_0 concept [85].

to radiation, and the dependence on the temperature of their response. Indeed, a cooling system had to be built in order to keep the huge detector under temperature variations lower than 0.1° to avoid eventual fluctuations in the response of the crystals.

These crystals, which had to be grown individually in laboratories, measure $2.2 \times 2.2 \times 23$ cm in the barrel and $3 \times 3 \times 22$ cm in the endcaps, and have therefore a length corresponding to around 26 radiation lengths, more than enough to stop even the most energetic particles. Since the light output of such crystals is quite low (only around 4.5 photoelectrons per MeV of energy), they have to be connected to both avalanche photodiodes and vacuum phototriodes in order to multiply the signal measured. Finally, these crystals have been mounted using a specific installation, slightly tilted with respect to both ϕ and η in order to remove any possible gap between two adjacent crystals.

The typical energy resolution of the ECAL installed at CMS is given by Equation 3.5 [85], accounting for several different effects, such as the stochastic nature of the observed scintillation, the electronics

and PU noise and the calibration and detector non-uniformity uncertainty.

$$\frac{\sigma_E}{E} = \sqrt{\left(\frac{2.8\%}{\sqrt{E}}\right)^2 + \left(\frac{0.12\%}{E}\right)^2 + (0.30\%)^2} \sim \frac{3 - 10\%}{\sqrt{E/\text{GeV}}} \quad (3.5)$$

Finally, a preshower layer has been set up just before the ECAL in order to reduce the possible mis-identification of events in which highly boosted pions could decay into two photons $\pi^0 \rightarrow \gamma\gamma$ as individual photons. This detector has been installed in the fiducial region ($1.653 < |\eta| < 2.6$) of the endcaps and is made of a lead layer, able to initiate the electromagnetic shower process, followed by two layers of silicon strips.

3.2.3 Hadronic Calorimeter (HCAL)

We know that charged hadrons do lose energy in a continuous when they traverse matter due to the ionization process and that all the hadrons strongly interact with the nuclei of any given medium. These principles are actually used in order to measure the energy of the hadrons produced by the LHC collisions using the Hadronic Calorimeter (HCAL) sub-system of CMS.

In this case as well, showers of particles due to a chain reaction are expected since the primary hadronic interaction will produce several additional hadrons, themselves interacting even more with the medium while losing energy. This hadronic kind of showers is characterized by the λ parameter, the nuclear interaction length, defined as the mean distance between two interactions of relativistic hadrons. The nuclear interaction length λ is usually much larger than the radiation length X_0 , resulting in a HCAL much larger than the ECAL.

A typical HCAL setup consists in alternating thick and high-density layers of absorber material, in which the showers can develop, and thin layers of active material used for the actual detection by sampling the energy deposition. This measurement is usually much less precise than the measurement provided by the ECAL, mostly since π^0 decaying into photons can appear in these showers, leading to an electromagnetic component of the shower that cannot be measured, and because around 30% of the incident energy is usually lost due to nuclear excitation and break-up effects [83]. In this case, the energy resolution can therefore be expressed using Equation 3.6.

$$\frac{\sigma_E}{E} > \frac{50\%}{\sqrt{E/\text{GeV}}} \quad (3.6)$$

In CMS, the HCAL, represented in Figure 3.10, is also divided into a barrel (HB), radially constrained between radii values of 1.77 meters (outer radius of the ECAL) and 2.95 meters (inner radius of the solenoid), and two symmetrical forward regions (HF) extending the pseudorapidities coverage from $|\eta| = 3$ to $|\eta| = 5.2$ and located at a distance of 11.2 meters to the PV. A final part composing the HCAL is the so-called Hadron Outer (HO), which has to be put outside of the solenoid in order to

increase the active material of the HCAL and therefore the effective nuclear radiation length λ .

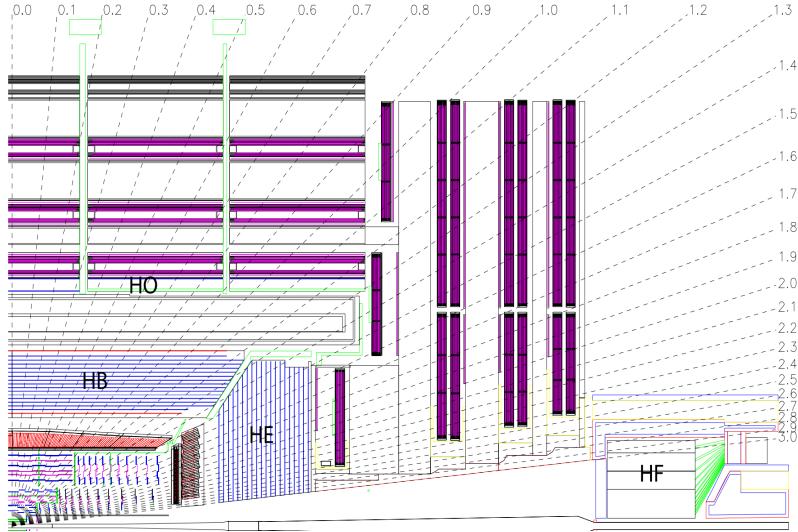

Figure 3.10: Schematic representation of the HCAL sub-system in CMS [85].

The HCAL barrel uses 36 identical azimuthal wedges as absorber, placed along the beam axis in such a way that the eventual cracks between them is smaller than 2 mm. The total absorber thickness at a 90° incidence angle is equal to only 5.8λ , which explains why the HO had to be added in order to increase this value to make sure to slow down and completely stop even the most energetic hadrons. The active medium of the HB is made out of 70 000 tiles able to collect the scintillation light, using the wavelength shifting fibre concept to measure the energy of the hadrons.

The barrel covers $|\eta|$ regions up to 1.3, while the coverage up to $|\eta| < 3.0$ is given by two endcaps on each side of the detector, placed in such a way to minimize the eventual cracks between the HB and the two HE. Finally, the HO, built in order to ensure adequate sampling depth at low pseudorapidities values, actually uses the solenoid itself as additional absorber material, since it is placed a bit outside of this coil. Its shape is constrained by the muon system and the mean fraction of recovered energy from the HO has been estimated to be equal to 0.38% for 10 GeV pions and up to 4.3% for 300 GeV pions, as shown in Figure 3.11.

3.2.4 Solenoid

The central piece of CMS is its extremely large (12.5 meters of length and 6 meters of diameter) and heavy (220 tons) superconducting solenoid able to produce a 3.8 T magnetic field, storing when active a huge energy of 2.6 GJ. It is the largest magnet of its type ever constructed, therefore allowing the tracker, ECAL and HCAL calorimeters to be placed inside the coil, resulting in a detector that is, overall, quite compact, compared to detectors of similar weight.

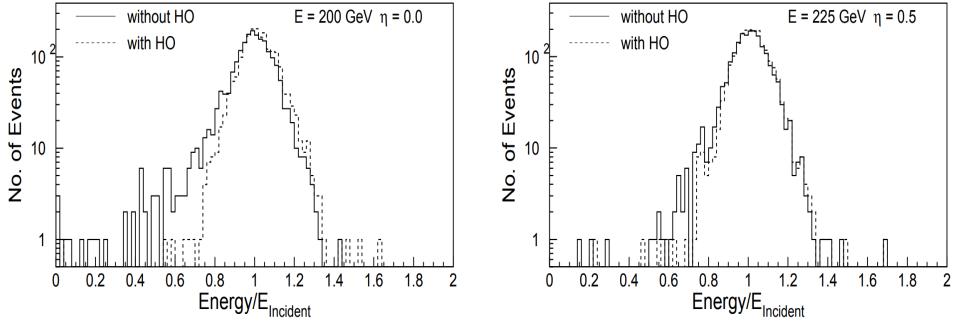

Figure 3.11: Distribution of the measured energy scaled to the incident energy for pions with incident energies of 200 GeV at $\eta = 0$ (on the left) and 225 GeV at $\eta = 0.5$ (on the right), with and without the inclusion of the HO in the HCAL system [85].

The magnetic field produced by this coil is extremely useful since it allows us to measure quite precisely the charge and the momentum of the different charged particles interacting with the detector just by measuring the curvature of their track, according to the Lorentz equation 3.7.

$$\vec{F} = q\vec{E} + q\vec{v} \times \vec{B} \quad (3.7)$$

The hoop strain $\epsilon = 130$ MPa applied throughout this solenoid is quite large compared to the strain applied on other previous detectors and this had to be taken into account during the conception of this magnet. It has then been designed in such a way that a large fraction of the CMS coil has a structural function, dividing the strain between the layers of the magnet and the support of the coil itself ($\sim 30\%$). At the end, the conductor of this solenoid, made from a Rutherford-type cable combined with aluminium, is mechanically reinforced with an aluminium alloy.

The coil of the magnet is then completed with a huge steel yoke return system, as seen in Figure 3.12, made out of 6 endcap disks and 5 barrel wheels, weighting in total more than 12 000 tons and therefore accounting for most of the weight of CMS. This system is composed of many steel blocks up to 620 mm thick combined, and actually also serves as the absorber plates of the muon detection system that will be described in the next section. A precise alignment system is then needed in order to hermetically close the detector and to make sure that the magnet is working efficiently each time the detector needs to be opened, usually once a year and during the Long Shutdowns (LSs).

Finally, a two pumping stations system has been put in place in order to setup a vacuum as strong as possible inside the 40 m^3 volume of the coil cryostat, and a helium refrigeration plant has been installed near the site of the detector, able to cool down the solenoid up to 4.5 K, giving a 2 K security margin with respect to the critical field of the superconducting coil. All these systems were extensively tested on the surface during the summer of 2006, before lowering down the complete solenoid in the experimental cavern where it now stands.

Figure 3.12: Picture of the solenoid system of CMS being setup in the assembly hall.

3.2.5 Muon system

The muon detection in a detector is extremely useful since many interesting processes are expected to produce such particles. Their detection and the correct measurement of their main properties such as their position and momentum is therefore crucial in most of the analyses performed.

Detecting muons is at the end of the day quite easy, as we will see, and the data extracted from them is usually more reliable than the one obtained from electrons since muons are less likely to be affected by the inner parts of the detector, such as the tracker, because of their low interaction cross section with usual matter.

The muon system of CMS is actually made out of three different gaseous sub-subsystems combined in order to perform a reconstruction as precise as possible of such particles over the entire kinematic range of the LHC. These different muon chambers systems do share some characteristics: they mostly have to be cylindrical, because of the geometrical shape of the inner systems of CMS and they have to be reliable and cheap, since they cover a total area of more than 25 000 m².

Let's now describe in details each category of muon chambers used in the different pseudorapidities areas, as shown in Figure 3.13, in order to form as muon system as hermetic as possible.

- First of all, in the barrel region, where the flux of muons is low and where the magnetic field is mostly uniform and low, the **Drift tubes (DTs)** have been installed. This system covers the $|\eta| < 1.2$ area and has been divided into 4 different layers, each containing a number of stations optimized in order to provide a full coverage of the θ angles, a good efficiency for the muon hits reconstruction into a single track and a good rejection of eventual background hits. This distribution of the DTs is represented in Figure 3.14.

The DT system is made out of 172 000 sensitive wires able to collect the residuals charges left by the ionization tracks of muons through the 250 chambers installed. The system has been set up in such a way that the maximal drift of any charge is lower than 21 mm, corresponding

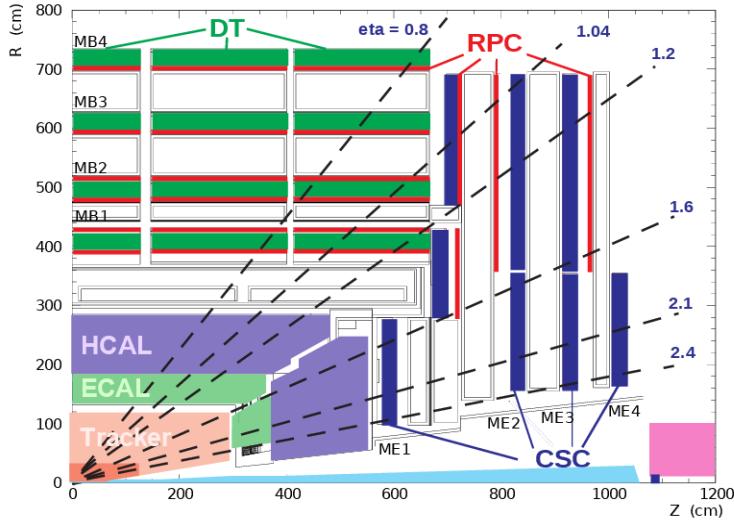

Figure 3.13: Geometrical repartition along the z-axis of the different muons chambers in CMS [87].

to a drift time of 380 ns in the gaseous chambers made out of 85% of Ar and 15% of CO₂, a value small enough to produce negligible occupancy in the different wires, to avoid the need of multi-hits electronics. Redundancy of the DTs provided by the installation of multiple layers is extremely important, mainly to reduce the backgrounds coming from eventual neutrons or photons, whose rate is actually much larger than the one obtained from prompt muons.

- In the two endcap regions, where the muon rates and the background levels are much larger and where the magnetic field is large and non-uniform, a different system had to be installed. First of all, the **Cathode Strip Chambers (CSCs)**, multiwire proportional chambers providing a fast response while being resistant to the radiation, are able to identify muons in a $0.9 < |\eta| < 2.4$ region (in the $0.9 < |\eta| < 1.2$ region, muons cross both DTs and CSCs while in the $1.2 < |\eta| < 2.4$ area, muons cross between 3 and 4 CSCs only).

This sub-system is made out of 540 different chambers in total, all perpendicular to the beam pipe. The sensitive plates of this sub-system are made out of 2 million wires, cover about 5000 m² and the total gas volume included in such chambers is equal to about 50 m³.

- Finally, some **Resistive Plate Chambers (RPCs)** have been added both to the barrel and to the endcap regions, in order to cope with the uncertainty associated with the eventual background rates and with the (in)ability of the previous muon system to identify unequivocally the correct bunch crossing when the LHC is running at full luminosity. Indeed, the time resolution of the DTs of 380 ns is way larger than the bunch spacing in the LHC, while a RPC is capable of tagging an ionizing event in less than 25 ns.

The RPCs are double-gap chambers operated in avalanche mode to ensure good operation at high rates and they are able to produce a fast response with good time resolution, even though its position resolution is worse than the one obtained with DTs or CSCs. The RPCs are also useful in the sense that they can help to resolve ambiguities in attempting to make tracks from multiple hits in a chamber.

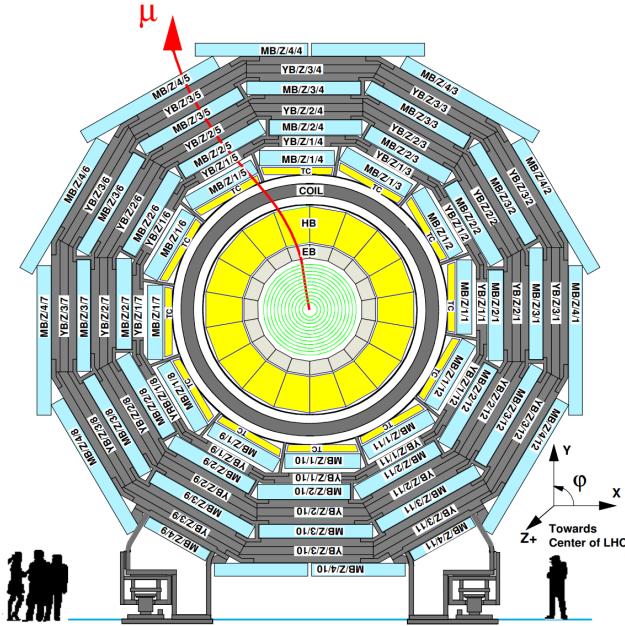

Figure 3.14: Lateral geometrical repartition of the different DT chambers in one of the 5 wheels of CMS [85].

Another advantage of the muon system such as the one built in CMS is that it can also directly be used by the trigger system, which will be described in Section 3.2.6, independently of the rest of the detector and in addition of being able to detect, identify and measure several properties of muons crossing it.

The muon reconstruction efficiency obtained by the muon system strongly depends on the pseudorapidity value of the muon considered, along with its transverse momentum, as shown in Figure 3.15. In this figure, we can also see that two different kinds of muons can be defined: the *standalone* muons, defined using only the data coming from the muon system, and the *global* muons, defined using both the information coming from the muon system and the tracker. Cross-checks between the different systems of CMS can therefore be performed, as will be described in Chapter 4.

Taking advantage of the Long Shutdown (LS) 2, a new muon system in CMS is currently being installed in the experimental cavern: the so-called Gas Electron Multipliers (GEMs), placed in the endcaps, where the radiation and event rates are the highest. This new sub-detector will provide additional redundancy and measurement points to the current system, therefore allowing a better muon track identification and reconstruction, and a wider coverage in the very forward region. The first 144 chambers, filled with a mixture of Ar and CO₂ and where the primary ionization due to incident muon is expected to happen, are currently being installed in the first disk of both endcaps (cf. Figure 3.16), while the rest will be set up during the next LS expected in 2024, before the phase II of operation of the LHC.

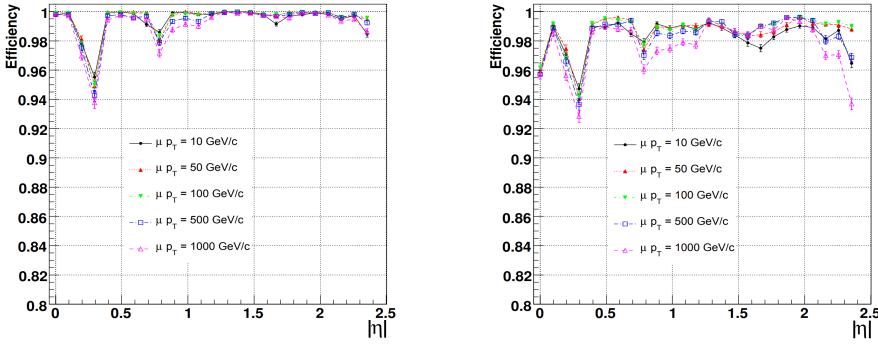

Figure 3.15: Muon reconstruction efficiency with different p_T and η values, considering only the muon system (on the left), and the combined information from the muon system and the tracker (on the right) [85].

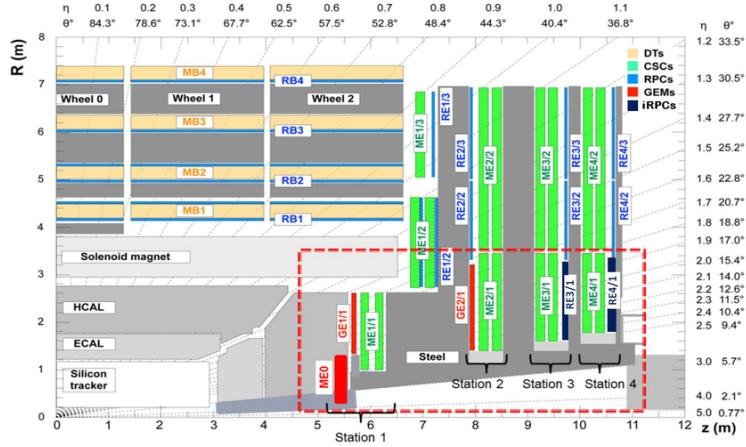

Figure 3.16: Location of the new GEM muon sub-system currently being installed in the very-forward region of CMS [85].

3.2.6 Trigger system

The CMS experiment is facing a data acquisition problem, since the huge collision rate delivered by the LHC (one bunch crossing each 25 ns, leading to an impressive rate of collisions of 40 MHz) is much larger than the data acquisition rate currently achievable by nowaday's electronics (around 1 kHz only, more or less equivalent to 1 Gb of data per second). It is therefore impossible to store and process all the collisions provided by the LHC ; instead, a selection needs to be made in order to select and record only the most interesting events.

A system, called the trigger system, has therefore been put in place in order to select 1 kHz of interesting events out the 40 MHz extremely quickly. This system is based on two different levels: first of all, the Level-1 Trigger (L1), a hardware set of electronics selecting around 100 kHz of data, followed by the High-Level Trigger (HLT), a software layer improving the selection even more. Let's now give a bit more details about these two levels of trigger:

- In order to maximize its efficiency, the Level-1 Trigger (L1) is implemented in different subsystems of the detector (on the calorimeters and muons system) and in the service cavern, just next to the detector, so that the electric signals do not have to travel large distances, therefore saving a few nanoseconds of decision time. This trigger, whose architecture is represented in Figure 3.17 gets new data each 25 ns, and today's electronics is not fast enough in order to deal with such a massive input of data, so an ingenious systems of buffers had to be put in place in order to put in line several events before analyzing all of them at once, using only basic segmented data provided by the detector.

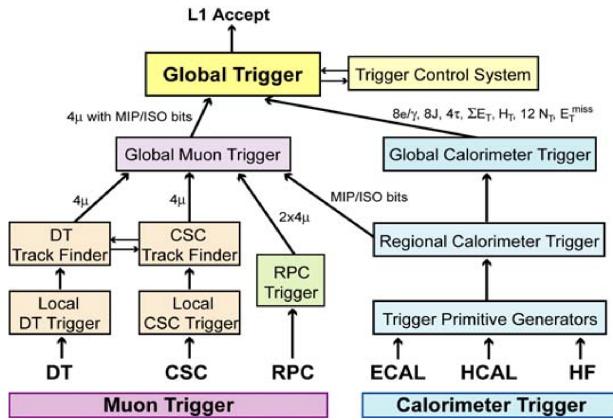

Figure 3.17: Architecture of Level-1 Trigger (L1) of CMS [85].

- On the other hand, the High-Level Trigger (HLT) does get access to the complete read-out data of the detector, since the rate has already been strongly reduced by the L1 Trigger, allowing it to perform complete calculations such as the ones that will be later performed by the different teams offline. Since this is a software based layer, it runs on a farm of computers and is in constant evolution, getting improvements each day in order to select and reconstruct in a better way and more efficiently interesting data from the collisions.

The HLT trigger is divided in several so-called *trigger paths*, especially developed in order to select a target object or physics process, usually with some p_T requirement in order to reduce the statistics collected by any given trigger, so that no to go past the bandwidth limit of 1 kHz. These triggers paths can then for example require the presence of one or two leptons, a jet whose p_T is higher to a certain threshold or the presence of Missing Transverse Energy (MET) in the event. If the selection implied by a trigger is too large, then it needs to be *prescaled*, meaning that its statistics is artificially reduced by forcing it to select one event every N, so that it does not use too much bandwidth: this is typically the case for trigger paths with low p_T requirements.

3.2.7 Data acquisition system

The CMS trigger system, along with its Data Acquisition System (DAQ), whose architecture is represented in Figure 3.18, has been designed in order to collect and analyze the data information at the nominal collision rate of 40 MHz and is feeded directly from the Level-1 Trigger (L1), meaning that it has to be able to read a flux of data of the order of 100 kHz (~ 100 Gb/s) coming from approximately 650 different sources at once, while providing enough computing power for the HLT to be able to reduce this rate by a factor ~ 100 .

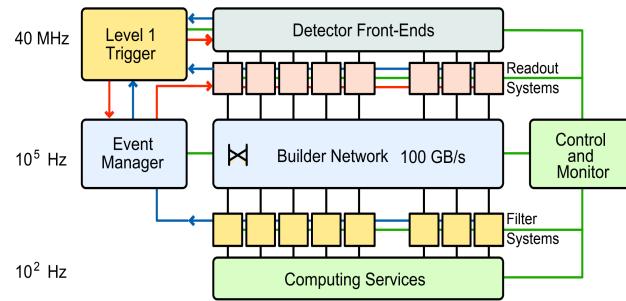

Figure 3.18: Architecture of CMS Data Acquisition System (DAQ) system [85].

The DAQ is also in charge of performing additional tasks, such as the generation of the Data Quality Monitoring (DQM) information resulting from online event processing in the HLT, the transfer of data from local storage at the CMS site to mass storage in the CERN data centre at the Meyrin site and the operation of the Detector Control System (DCS) system, ensuring the correct operation of the detector and a high quality data taking at all times.

3.5	Schematic representation of the CMS coordinate system used by convention.	46
3.6	Schematic representation of the CMS tracker, for different pseudorapidity values and along the z-axis [86].	47
3.7	Tracker reconstruction efficiency of muons (on the left) and pions (on the right) for different pseudorapidities and particle momenta (1, 10 and 100 GeV) [85].	48
3.8	Schematic representation of the CMS ECAL [85].	49

3.9 Schematic representation of a typical electromagnetic shower and the radiation length X_0 concept [85].	49
3.10 Schematic representation of the HCAL sub-system in CMS [85].	51
3.11 Distribution of the measured energy scaled to the incident energy for pions with incident energies of 200 GeV at $\eta = 0$ (on the left) and 225 GeV at $\eta = 0.5$ (on the right), with and without the inclusion of the HO in the HCAL system [85].	52
3.12 Picture of the solenoid system of CMS being setup in the assembly hall.	53
3.13 Geometrical repartition along the z-axis of the different muons chambers in CMS [87].	54
3.14 Lateral geometrical repartition of the different DT chambers in one of the 5 wheels of CMS [85].	55
3.15 Muon reconstruction efficiency with different p_T and η values, considering only the muon system (on the left), and the combined information from the muon system and the tracker (on the right) [85].	56
3.16 Location of the new GEM muon sub-system currently being installed in the very-forward region of CMS [85].	56
3.17 Architecture of Level-1 Trigger (L1) of CMS [85].	57
3.18 Architecture of CMS Data Acquisition System (DAQ) system [85].	58
